Zusammenfassung

Metallische Nanopartikel und ihre Oxide (z.B. ZnO NP, TiO₂ NP und Fe₂O₃ NP) werden aufgrund ihrer chemischen und physikalischen Eigenschaften häufig als Additive in der Reifenproduktion, in Katalysatoren, Lebensmitteln, Arzneimitteln und Kosmetikprodukten verwendet. Künftig wird ein kontinuierlicher Anstieg der industriellen Anwendung (~ 1663 Tonnen im Jahr 2025) mit gesteigerter Freisetzung in die Umwelt erwartet, was zwangsläufig zu einer vermehrten Aufnahme über das respiratorische Epithel führt. Metalldampffieber ist als gesundheitsschädigender Effekt von Metalloxid-haltigen Aerosolen (z.B. ZnO) nach Inhalation bekannt. Immunreaktionen, wie beispielsweise Entzündungen, werden häufig mit der Entstehung von Sauerstoffradikalen (ROS) in Verbindung gebracht, die wiederum zu DNA-Schäden führen können. Drei mögliche Ursachen der Genotoxizität werden angenommen: direkte Interaktion von Nanopartikeln mit intrazellulären Strukturen, Interaktion von Ionen dissoziierter Partikel mit intrazellulären Strukturen sowie die Entstehung von ROS initiiert durch Partikel oder Ionen.

Die vorliegende Studie befasst sich mit den Mechanismen der Genotoxizität von ZnO Nanopartikeln (ZnO NP), als Beispiel für metallische Nanopartikel, im respiratorischen Epithel. In der Studie wurde gezielt die intrazelluläre Aufnahme und Verteilung von ZnO NP, deren Toxizität, deren DNA schädigendes Potential sowie die Aktivierung der *DNA damage response* (DDR) analysiert.

Es konnten kaum internalisierte ZnO NP mittels TEM detektiert werden. Innerhalb der ersten Sekunden nach Behandlung mit ZnO NP wurde spektrofluorometrisch ein starker Anstieg der intrazellulären Zn²⁺ Konzentration gemessen. In unbehandelten Zellen war Zn²⁺ in granulären Strukturen lokalisiert. Die Behandlung mit ZnO NP führte zu einer Akkumulation von Zn²⁺ in diesen Strukturen. Im zeitlichen Verlauf verlagerten sich die Zn²⁺-Ionen in das Zytoplasma, sowie in Zellkerne und Mitochondrien. Es wurde keine Kolokalisation von Zn²⁺ mit den frühen Endosomen und dem endoplasmatischen Retikulum beobachtet. Die Vorbehandlung der Zellen mit *Diethylen-triamin-pentaessigsäure* (DTPA), als extrazellulärem Komplexbildner, verhinderte den intrazellulären Anstieg von Zn²⁺ nach Behandlung mit den Partikeln.

Die Behandlung mit ZnO NP resultierte in einer zeit- und dosisabhängigen Reduktion der zellulären Viabilität, während die intrazelluläre ROS-Konzentrationen in den ersten 30 min leicht und anschließend kontinuierlich bis zum Ende der Messung anstiegen. Außerdem verringerte sich das mitochondriale Membranpotential, während sich die Anzahl der frühapoptotischen Zellen in einer zeitabhängigen Weise erhöhte.

Zusammenfassung

DNA Doppelstrangbrüche (DNA DSB) wurden mittels Immunfluoreszenz-Färbung der γ H2A.X foci sichtbar gemacht und konnten nach Behandlung mit ZnO NP detektiert werden. Die Vorbehandlung mit dem Radikalfänger *N-Acetyl-L-Cytein* (NAC) resultierte in stark reduzierten intrazellulären ROS-Konzentrationen sowie wenigen DNA DSB. Die DNA Schädigung wurde durch Vorbehandlung mit DTPA ganz verhindert.

Die Aktivierung der DDR wurde durch die Analyse von ATM, ATR, Chk1, Chk2, p53 und p21 mittels Western Blot und ELISA nach Behandlung mit ZnO NP überprüft. Der ATR/Chk1 Signalweg wurde durch ZnO NP nicht aktiviert. Die Komplexierung von Zn^{2+} resultierte in einer verminderten ATM/Chk2 Signalwegaktivierung. Es zeigte sich, dass das Abfangen von ROS keinen Effekt auf die ATM/Chk2 Signalwegaktivierung hatte.

Zusammengefasst wurde festgestellt, dass die Exposition mit ZnO NP in der Entstehung von ROS, reduzierter Viabilität und vermindertem mitochondrialem Membranpotential resultiert, sowie zeitabhängig eine frühe Apoptose initiiert. ZnO NP dissoziierten extrazellulär und wurden schnell als Zn^{2+} über unbekannte Mechanismen internalisiert. Die Zn^{2+} -Ionen wurden im Zytoplasma, sowie besonders in den Mitochondrien und dem Zellkern, akkumuliert. Die DDR Signalgebung wurde durch ZnO NP aktiviert, jedoch nicht durch NAC inhibiert. Es wurde gezeigt, dass DTPA die DDR Aktivierung komplett inhibierte. Die Behandlung mit ZnO NP induzierte DNA DSB. Die Inhibition von ROS reduzierte die DNA DSB und die Komplexierung der Zn^{2+} verhinderte die Entstehung von DNA DSB.

Diese Daten sprechen für die Dissoziation der Partikel und die hierbei freigesetzten Zn^{2+} als Hauptmediator der Genotoxizität metallischer Nanopartikel.

Abstract

Metallic nanoparticles including their oxides (e.g., ZnO NP, TiO₂ NP, and Fe₂O₃ NP) are widely used as additives in rubber industry, catalysts, foods, pharmaceuticals and cosmetics, because of their chemical and physical properties. Prospectively, a continuous rise of industrial application (~1663 tons in 2025) is estimated with an increasing release into the environment, and further unavoidable intake by humans e.g., through the respiratory epithelia. Acute metal fume fever is known as an adverse health effect of aerosol inhalation containing metal oxides (e.g., ZnO). Immune responses such as inflammation are often associated with the generation of reactive oxygen species (ROS), which possibly initiate DNA damages. Three reasons of genotoxicity are assumed: direct interaction of nanoparticles with intracellular structures, interactions of dissociated ions from particles, and the generation of ROS initiated by the particles or ions.

The present study paid particular attention to the mechanisms of genotoxicity in respiratory epithelia exposed to zinc oxide nanoparticles (ZnO NP), as example for metallic nanoparticles. The study aimed to investigate the intracellular ZnO NP uptake and distribution, toxicity, DNA damaging potential, and DNA damage response (DDR) activation.

Internalized ZnO NP were infrequently detected by TEM. Strongly increased intracellular Zn²⁺ levels were measured in the first seconds after treatment with ZnO NP by spectrofluorometry. In untreated cells Zn²⁺ is located in granular structures at basal levels. Treatment with ZnO NP led to an accumulation of Zn²⁺ in these structures. In the period of time, Zn²⁺ shifted to the cytoplasm, nucleus, and mitochondria. No co-localization of Zn²⁺ with early endosomes and endoplasmatic reticulum was detected. Pretreatment of the cells with the extracellular chelator *diethylene triamine pentaacetic acid* (DTPA) prevented intracellular Zn²⁺ increase after particle treatment.

ZnO NP treatment resulted in a time- and concentration-dependent reduction of cellular viability, while ROS-levels increased slightly in first 30 min and continuously afterwards until end of measurement. Furthermore, the mitochondrial membrane potential decreased whereas the amount of early apoptotic cells raised in a time-dependent manner.

DNA double strand breaks (DNA DSB) were detected after ZnO NP treatment by visualization of γH2A.X foci. Pretreatment with the ROS scavenger *N-acetyl-L-cysteine* (NAC) resulted in strongly decreased intracellular ROS-levels as well as reduced DNA DSB. However, pretreatment with DTPA prevented DNA damages entirely.

Abstract

The activation of the DDR was shown by analysis of ATM, ATR, Chk1, Chk2, p53, and p21 after ZnO NP exposure performing Western blots and ELISA measurements. In contrast, the ATR/Chk1 pathway was not activated by ZnO NP. The complexation of Zn²⁺ resulted in impaired ATM/Chk2 pathway activation. However, ROS scavenging had no effect on ATM/Chk2 pathway activation, i.e., signaling remained activated.

Altogether, it was found that ZnO NP treatment resulted in increased intracellular ROS-levels, reduced viability and decreased mitochondrial membrane potential, and they initiated early apoptosis in a time-dependent manner. ZnO NP dissociated extracellular and Zn²⁺ were quickly internalized by an unknown mechanism. The Zn²⁺ ions were accumulated in the cytoplasm, the nucleus, and the mitochondria. DDR signaling was activated by ZnO NP but not inhibited by NAC, while a completely inhibition of DDR activation was shown after pretreatment with DTPA. Treatment with ZnO NP generated DNA DSB. ROS scavenging reduced DNA DSB, and Zn²⁺ complexation prevented DNA DSB.

These data suggest particle dissociation and the released Zn²⁺ seems to be the main mechanism of metallic nanoparticle genotoxicity.

UV-A	ultraviolet A
UV-B	ultraviolet B
W	watt
w/w	% weight/weight
xbp-1s	X-box binding protein 1s
xg	gravitational force
XPA	DNA repair protein complementing XP-A cells
XRCC4	DNA repair protein XRCC4
XRD	X-ray diffraction
Zim17	zinc finger motif protein of 17 kDa
ZIP	zinc importers
Zn	zinc
ZnCl ₂	zinc chloride
ZnO NP	zinc oxide nanoparticle(s)
ZnT	zinc exporters
$\Delta\Psi_m$	mitochondrial membrane potential

1 Introduction

1.1 Nanotechnology

Nanomaterial is commonly defined as an object of 1-100 nm in one or more dimensions including nanofibers, nanogels, nanotubes, and nanoparticles¹. The diameter of a nanoparticle is corresponding in size to approximately 500 atoms. Furthermore, in a biological view it has the dimension of enzymes and receptors^{2,3}. The environmental behavior of nanoscaled material is often different to their bulked material⁴⁻⁶. Nanoparticles show changes in their properties due to an increased surface to volume ratio compared to their bulk material. The chemical reactions take place on the particle surface and in comparison to bulk material, nanoparticle have an increased chemical, biological, and catalytically behavior. In 2015, earnings of \$ 1 trillion in this sector are predicted and 5.3 % of these industrial products are related to medical applications^{7,8}. In the last decade 485 companies in 24 countries have been established and brought more than 1000 products to market^{7,9}. In contrast to the benefits of nanoscaled materials, many scientists have increasingly concerns about the environmental release (estimated ~500 tons in 2009 in the U.S.) and linked possible adverse health effects¹⁰.

1.1.1 Metal oxide nanomaterials

Many metals and metal oxides are able to form nanoscaled materials. Metallic nanoparticles have many useful properties and have been used since the middle ages (e.g., ornamental decoration) in the form of colloids or soils¹¹. They display enhanced optical, electrical, chemical or magnetic qualities. Metal and metal oxide nanoparticles can be easily synthesized from bulk material and modified on their surface (e.g., conjugated antibodies, ligands), which opens a wide range of applications¹². There are two main approaches for fabricating metal oxide nanoparticles or manipulating devices, the bottom up and the top down principal. The bottom up path refers to the build up of a nanomaterial from the bottom, i.e., atom by atom. In contrast the top down approach refers to slicing or cutting bulk material into nanoscaled material^{13,14}. Metal oxide nanoparticles are the most highly used nanoparticles in industrial applications. The global market report for metal oxide nanoparticles (2013) estimates an increase from 270,041 tons in 2012 to 1663,168 tons in 2025¹⁵. The mostly used metal oxide nanoparticles in consumer products are SiO₂ NP, TiO₂ NP, and ZnO NP¹⁶. *Ivask et al. (2015)* showed that SiO₂ NP, TiO₂ NP, and ZnO NP have toxic effects on different cell lines¹⁷. *Brunner et al. (2006)* suggested that ZnO NP may easily dissolve and the particles show therefore an enhanced toxic behavior¹⁸. The industrial application of metal

oxide nanoparticles is booming and has promising characteristics but also possible adverse effects as hypothesized for e.g., ZnO NP.

1.1.2 Zinc oxide and its application in industrial production

The annual production of zinc oxide (ZnO) is more than 1.2 million of tons worldwide. Far East, especially China, is by far the biggest producer and processor with 38 %, followed by the European Union with 31 % (Figure 1A)¹⁹. ZnO is widely used as an additive in industrial production, e.g., rubber industry, ceramic and glass compositions, catalysts, foods, pharmaceuticals, and cosmetics (Figure 1B)²⁰. According to different sources, the global annual production of nanoscaled ZnO is estimated between ~ 500 and 33,400 tons^{13,16,21}. ZnO is a multifunctional inorganic compound and has interesting chemical and physical properties such as a wide range of UV absorption, high photostability, biocompatibility and biodegradability^{14,19,20,22}. Pure microcrystalline ZnO is a white inorganic salt and has a molecular weight of 81.37 g/mol. ZnO is reacting amphoterically with alkalis and acids²⁰. ZnO is used in food industry as a substitute for zinc as an essential trace element. The antimicrobial and UV protective properties of ZnO make it a perfect component in industrial production of food packing material. In pharmaceuticals ZnO is often used because of its antiseptic properties in powders, creams and ointments, especially for babies. ZnO strongly absorbs UV light and is therefore applied in sunscreens. This versatile utilization in industrial production leads to an increased implementation in daily life and an increased environmental release.

Figure 1: Application and worldwide distribution of ZnO

(A) Worldwide distribution of ZnO production and application. The Far East, especially China, is the most dominant supplier of ZnO (approx. 38 %). It is followed by Europe (approx. 31 %) and North America (approx. 18 %). (B) Rubber production is the most important application of ZnO (e.g., tires). A further utilization is the ceramic industry followed by chemical and electronic production. The total use of ZnO in pharmaceuticals is less than 10 % but is expected to increase, due to its wide range of application (adapted from:^{19,20}).

1.2 Mechanisms and consequences of particle uptake

Increasing industrial manufacture and use of nanoscaled materials lead to environmental release and therefore enrichments in air, soil, water, and plants, followed by an unavoidable exposure to humans. The amounts of nanomaterial intake for humans depend on the level of deposition, injection, inhalation or ingestion over the skin, gastrointestinal- or respiratory tract (Figure 2). The nanoparticle uptake depends on particles size, concentration and surface modification.

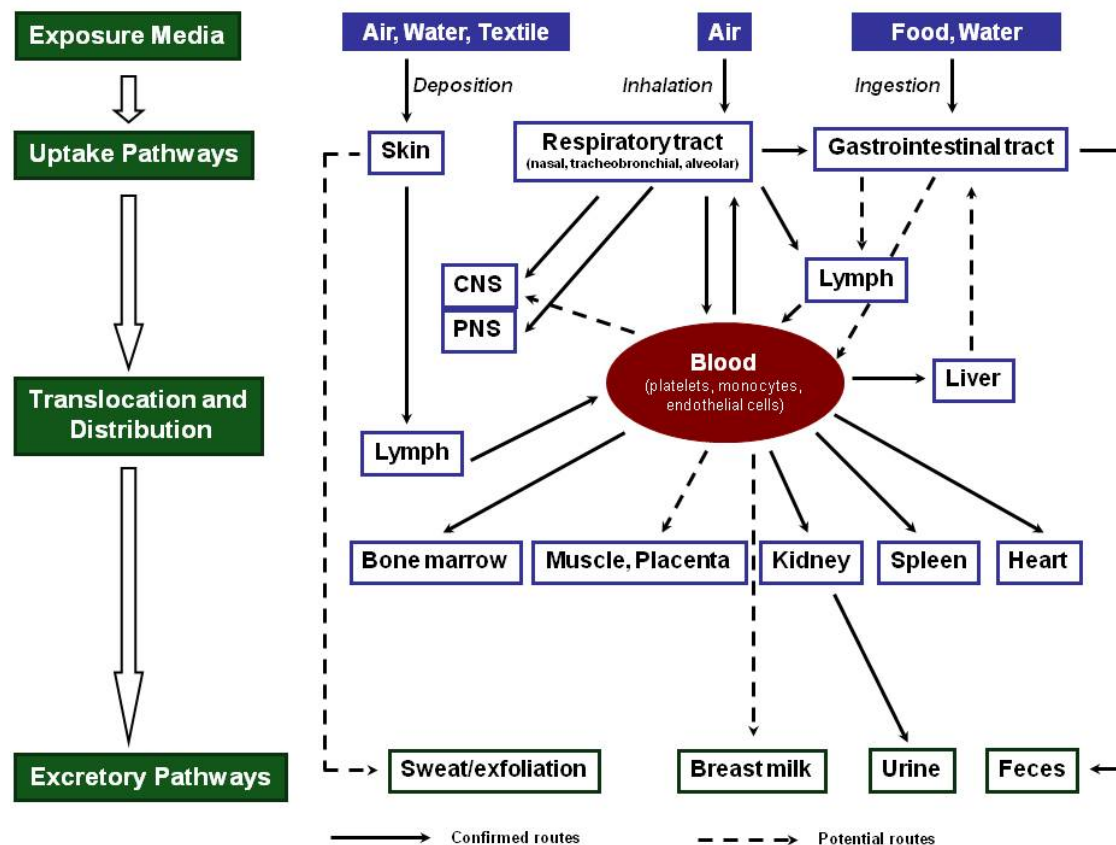

Figure 2: Uptake and translocation pathways of nanomaterial

Nanoparticles can be taken up by deposition, inhalation or ingestion. The illustration gives an overview of already investigated uptake routes (cf. confirmed \longrightarrow) and hypothetical routes (cf. potential $-\ - - \longrightarrow$) of nanoparticles. The primary uptake pathways are through the skin, gastrointestinal and respiratory tract. After assimilation, the particles are translocated in the blood and further directly or indirectly distributed to the organs. The distribution rates are still unknown and need to be established. The uptake mechanisms as well as the translocation and distribution are dependent on physico-chemical characteristics of the nanomaterial. The affiliated particles may get excreted by sweat, exfoliation, breast milk, urine and feces (adapted from:²³).

1.2.1 Skin

Nanoparticles are used in many cosmetics and textile products, resulting in a direct contact to the human skin. ZnO NP are utilized as inorganic filters in sunscreens like TiO₂. These compounds can reflect and absorb UV light, especially UV-A and UV-B radiation. Due to its antibacterial effects, ZnO is frequently used as a component in cosmetics, pharmaceutical creams, and shower gels. Therefore, possible deposition in the skin has been investigated in recent studies²⁴⁻²⁶. ZnO in sun blocker was identified as a reducer of cellular viability in keratinocytes²⁷. The accumulation of particles in the skin is depending on size, surface, and skin integrity. New findings demonstrate a deposition of particles in the upper dermal layer, but single particles are penetrating to the lymph and further to the blood system^{24,26,28,29}. Despite these data, ZnO NP in cosmetic products are still classified as harmless^{24,26,30}.

1.2.2 Gastrointestinal tract

The gastrointestinal tract (GI) represents another uptake pathway of ingested nanoparticles. The kinetics of particle distribution depend on the metabolic pathways by persorption in the extrusion zone, passage over tight junctions, and receptor-mediated endocytosis of enterocytes or transcytosis by M cells of the peyer's plaques³¹⁻³⁴. An animal study, published by *Szentkuti et al. (1998)*, showed that particles with a cationic surface charge were caught by the mucosa, while the carboxylated particles were taken up by diffusion³⁵. Swallowing contaminated food with nanomaterial may lead to GI damage³⁶. Studies on enterocytes of *Xenopus laevis* showed an impact of metallic nanoparticles, especially ZnO NP on ROS generation, inflammation, and necrosis³⁷.

1.2.3 Respiratory tract

The respiratory tract, with a surface area of 1400 m², is besides the skin (2 m²) and the gastrointestinal tract (200 m²), the primary contact organ with the environment³⁸. The lung has an total average lung capacity of 6 L and is therefore the main entry pathway of nanoscaled materials^{33,38,39,40}. The respiratory tract is divided into the upper and lower region. The upper region includes the nose, paranasal sinuses, pharynx and a part of the larynx (above the vocal cords), known as airways. The airways comprise a distance of 2.300 km and transport the air inside and outside the human body. Due to its viscous layer, it is a barrier between air and blood³⁹. The lower region includes the larynx (below the vocal cords), trachea, bronchi and bronchioles. This lower respiratory tract is also known as alveoli. 300x10⁶ alveoli are located in the lung, which are responsible for gas

1 Introduction

exchange³⁹. The area of gas exchange and the blood capillaries are separated by a thin wall of about 0.5 micron. Because of the large surface area of the alveoli, protection against the environmental intake (e.g., nanoparticles) is worse compared to the airways³⁹. Oberdoerster *et al.* (1995) demonstrated significant differences between nanoparticles and larger particles (known as bulk material) of inhaled material in deposition and clearance²³. The fractional deposition of inhaled particles in the nasopharyngeal/laryngeal, tracheobronchial and alveolar region of respiratory tract was analyzed^{23,41}. Inhaled particles between 1 nm and 50 nm are enriched in all regions, while larger particles (> 1 μm) are mainly deposited in the nasopharyngeal area (Figure 3)^{23,41}.

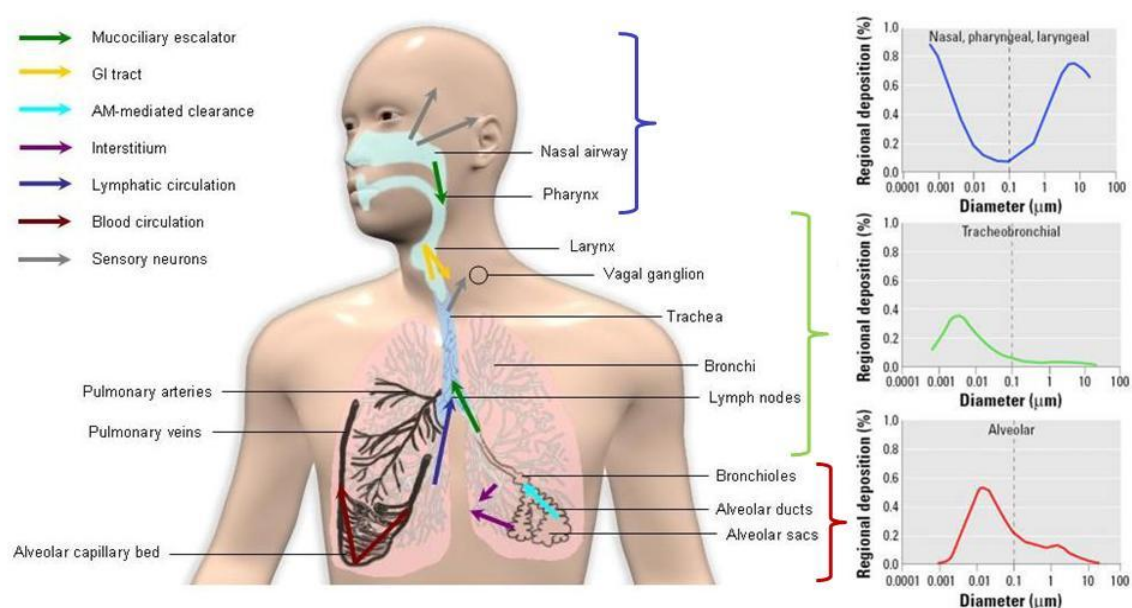

Figure 3: Pathways of nanoparticle clearance and deposition in the respiratory epithelia

The different arrows show possible clearance pathways of the respiratory epithelia. Possible depositions of inhaled nanoparticles during nose breathing are shown for the nasopharyngeal (blue), tracheobronchial (green) and alveolar region (red) of the respiratory epithelia. The clearance as well as the deposition is dependent on size and surface modifications of nanomaterial (adapted from:^{18,23,41}).

The upper airways possess a mucociliary clearance that exports inhaled particles³⁹. The classical clearance pathways are demonstrated in Figure 3. Biosoluble nanomaterials may undergo a chemical clearance due to extra- or intracellular milieu (pH)²³. In the alveoli the clearance of particles smaller than 2.5 μm is cell mediated by phagocytosis of macrophages^{33,39,42–46}. Alveolar epithelial cells are divided into type I cells with a direct connection to vascular endothelial cells and the surfactant producing type II cells⁴⁷. The surfactant proteins are known for their pathogen opsonising function and affect on

phagocytosis. The activation of macrophages results in the release of immune mediators such as cytokines, chemokines and reactive oxygen species (ROS)^{33,34,38,39,42,44,45}. Nanoparticles can overcome the defence mechanisms in dependence of their characteristics, concentration and exposure time. *Jachak et al. (2012)* discovered that small nanoparticles are naturally stuck in mucosa, but for some metal oxide nanoparticles, especially ZnO NP, an uptake in epithelial cells was observed⁴⁸. The inhalation of nanoparticles may lead to lung diseases as shown for ZnO NP. The exposure to ZnO NP showed an increased occurrence of observed goblet cells and histological changes of pulmonary tissue associated with fibrosis in rats⁴⁹. Furthermore, the inhalation of certain metal oxides (e.g., ZnO) may cause metal fume fever associated with symptoms such as fever, chills, headache and fatigue⁵⁰⁻⁵². *Vandebriel et al. (2012)* reviewed different studies on mammalian nanoparticle toxicity and illustrated that inhalation or instillation of ZnO NP leads to lung inflammation and systemic toxicity⁵³.

1.2.4 Cellular uptake of nanomaterials

Mammalian cells use the energy-dependent process of endocytosis to receive energy or communicate with their biological environment by internalization of nutrients and signaling molecules^{54,55}. There are four pathways for cellular uptake of nanoscaled material called clathrin/caveolar mediated endocytosis, phagocytosis, micropinocytosis and pinocytosis. Efficiency of nanoparticle internalization is dependent on their physico-chemical properties such as size, surface chemistry and shape. The clathrin/caveolar mediated endocytosis is the most important pathway for nanomaterials, because of an immediately covering of nanoparticles with plasma proteins gathering physiological solutions⁵⁵⁻⁵⁸. This process is receptor-mediated and enables a cellular uptake of small particles with a maximum size of 100 nm in diameter⁵⁹. The pathway of phagocytosis is actin-dependent and used by phagocytic cells, which internalize particles larger than 0.5 μm ^{55,60}. The micropinocytosis and pinocytosis are an unspecific internalization mechanism of fluids and small nanoparticles (< 10 nm)⁶¹. The endocytic mechanism comprises distinct membrane compartments. Early endosomes (EE) are rapidly formed and usually located in the cytoplasm close to the plasma membrane, serving as a focal point of endocytosis and absorb vesicles from the cellular surface⁶². The main attributes of EE are the mildly acid environment and tubule-vesicular structure associated with their sorting function of dissociated ligands for further endocytic steps⁶². Late endosomes (LE) adhere to different membrane vesicles and proteins (e.g., acid hydrolases) receiving the pre-sorted material of the EE. The LE are acidic with a pH of 5.5 mediating a final merging prior to lysosomal transfer⁶³. The pH of lysosomes (L) is at 4.8, which implodes

carbohydrates, fats, proteins and cellular waste in usable compounds for cellular functions⁶⁴. In contrast to endocytic pathway, exocytosis involves the fusion of secretory vesicles with the inner surface of the plasma membrane and the releases of their content into the extracellular space⁶⁵. Internalized nanoparticles can exit the cell via exocytosis by lysosomal-, vesicle-related- and non-vesicle-related secretion⁵⁵. The regulated exocytic pathway enables a fast response of already existent vesicles and is generally triggered by a high concentration of free cytosolic Ca^{2+} ⁶⁶⁻⁶⁹. The particle uptake is dependent on several factors such as form, size, surface charge, cell type, cell culture medium, and particle surface modification^{48,53,70}. The cellular uptake of ZnO NP is rarely observed. Two possibilities are the ZnO NP uptake as well as the uptake of Zn^{2+} dissociated from the particles. *Hackenberg et al. (2011)* observed an uptake of ZnO NP and an agglomeration inside the cytoplasm and nucleus but they coated the particles with BSA reducing particle dissociation⁷¹. *Kao et al. (2012)* hypothesized an endosomal uptake for ZnO NP and a fast dissociation of the particles due to the acidic pH of endosomes⁷².

Figure 4: Cellular uptake and release of nanoparticles

Four different types of cellular nanoparticle entry are described. The nanoparticles enter the cell by clathrin/caveolar mediated endocytosis, macropinocytosis, phagocytosis and pinocytosis. After affiliation, the particles can deposit the intracellular space or can be secreted by lysosomes, by vesicles or in a non vesicle/lysosomal associated pathway (adapted from:⁵⁵).

1.3 Nanotoxicity

Within the last two decades, the discipline of nanotoxicology has been developed in line with the rapid engineering of nanotechnology. Although the environment and humans have been exposed to respirable dust throughout their evolutionary stages, the anthropogenic sources of nanomaterials have drastically been increased during the last decade²³. Risk assessments of nanoscaled material are still unsatisfactory investigated and more information about the safety and the potential hazards are urgently needed²³. Therefore, the nanotoxicology is a “sub domain” of toxicology which is defined as the effects of nanosized material impacting environmental condition and human health. The toxicological effect of nanomaterial could be observed in the case of synthetically produced particles as well as in by-products of burnt and fractionated material^{73,74}. The research of nanotoxicity has shown a remarkable complexity of cellular interactions with nanomaterials. Researchers address the interactions of the release focusing on the physico-chemical properties of the nanoparticles. Possible mechanisms of nanotoxicology are inflammation, ROS generation, direct structural interactions, DNA damages, apoptosis, and the effect of released ions.

1.3.1 Inflammatory potential of nanomaterial

Inflammation is a central process of nanoparticle-induced adverse health effect⁷⁵. The inflammatory potential of inhaled metal oxides has been established for decades as acute metal fume fever syndrome^{50,52}. The exposure to ZnO NP is accompanied by an impressive pulmonary cellular response, characterized by the appearance of short time symptoms after inhalation and healing of metal fume fever within 24 h⁷⁶. The tissue inflammation is initiated and regulated by cytokines, a class of signaling molecules. Cytokines are involved in many signaling processes including cell growth, -differentiation, and the recruitment of immune cells⁷⁷⁻⁷⁹. *McCreanor et al. (2007)* investigated effects of diesel exhaust on respiratory epithelia and observed inflammatory responses predominantly induced by neutrophils with increased levels of IL-8 and myeloperoxidase in the supernatant of the sputum⁸⁰. Further, the exposure of pulmonary dendritic cells to ZnO NP as component of exhausts resulted in secretion of cytokines⁸¹.

1.3.2 ROS generated by nanomaterials

ROS is a collective term which summarizes molecules with at least one unpaired electron assigning reactivity to a variety of biological targets. They are also defined as free radicals which naturally arise as by-product of anaerobe metabolism characterized

by a high instability. The class of ROS contains the O₂-derived free radicals called superoxide anion ($\bullet\text{O}_2^-$), hydroxyl ($\text{HO}\bullet$), peroxy ($\text{RO}_2\bullet$), and alkoxy ($\text{RO}\bullet$) as well as the O₂-derived nonradical species such as hydrogen peroxide (H_2O_2) and hypochlorous acid (HOCl)^{82–85}. High doses of ROS often induce cellular damages to DNA, proteins and lipids, which is summarized as oxidative distress, while low levels serve as regulator molecule in biological redox signaling^{86,87}. Endogenous sources of ROS by-products of cellular metabolism and respiration are generated by NADPH oxidases. Organelles, such as mitochondria or peroxisomes, produce hydrogen peroxide as a by-product using enzymes (e.g., p450 cytochromes), which catalyze the oxidative reduction⁸⁸. During the cellular respiration in mitochondria, oxygen is reduced in a gradual electron transport chain⁸⁸. Exogenous sources of ROS are generated by chemical and physical exposures e.g., pollutants, smoke, radiation and metals⁸⁹. Recent studies suggested possible harmful activities of metals (e.g., Zn^{2+} , Fe^{2+}) through the modulation of the intracellular redox state, at least in part of Fenton and/or Haber-Weiss reactions^{52,90}.

Figure 5: Fenton reaction as exemplified for iron ions

The dissociated ions possibly enhance the production of ROS in mitochondria through disregulated $\Delta\Psi_m$ and autooxidation of thiol groups⁹¹. The human body has developed different defense mechanisms against ROS. Antioxidant enzymes (e.g., SOD) as well as scavengers (e.g., glutathione) are avoiding the oxidative degradation⁸⁸. The relation between glutathione (GSH) and oxidized glutathione disulfide (GSSG) serves as sensor for an imbalance between ROS and the intracellular defense mechanisms. *Walther et al. (2000)* showed that Zn^{2+} are able to inhibit the glutathione reductase which further synergistically enhanced the oxidative stress⁹². In case of an insufficient defense the ROS sensitive MAPK- and NF- κ B signaling is activated to induce the expression of proinflammatory cytokines, chemokines and adhesion molecules⁹³. Continuously generated ROS and reduced scavenging by antioxidants lead to increased oxidative distress. This cellular situation is associated with many health impairments such as cardiovascular, neurological or psychiatric diseases and cancer^{87,94–96}. However it is not proven, whether the generated oxidants trigger the disease or ROS is induced as a side effect of the disease⁹⁷.

1.3.3 Interaction of nanoparticles with intracellular structures

After cellular uptake and penetration of the particles through the plasma membrane, different interactions between the nanoparticles and the intracellular structures are conceivable. Researchers suggested the direct interaction of nanoparticles with cellular structures as possible toxic mechanism. *Moschini et al. (2013)* detected an interference of mitochondrial and lysosomal functions as well as an impairment of the mitochondrial membrane after particle treatment as evidence of a direct particle-cell-interaction⁹⁸. Beside the generation of energy through oxidative phosphorylation of ATP, the mitochondria are necessary for important cellular regulations such as apoptosis and cellular calcium and redox homeostasis^{99–101}. The effect of nanoscaled materials on mitochondria has diverse consequences to cellular viability and depends on particle size and surface chemistry. Different studies have shown that colloidal Ag-coated gold NP, black copolymer micelles and multi-walled nanotubes of approximately 50 nm are aggregated nearby or even inside the mitochondria^{23,102–106}. Another study demonstrated that gold NP (3 nm, diameter) penetrate through the outer mitochondrial membrane via voltage-dependent anion channels. *Salnikov et al. (2007)* and others interpret these observations according to the mitochondrial swelling, permeability transition, morphology changes, intracellular Ca^{2+} influx and loss of cristae^{93,105,107}. *Qi et al. (2005)* observed a loss of mitochondrial membrane potential ($\Delta\Psi\text{m}$) in gastric carcinoma cells induced by chitosan NP¹⁰⁸. The $\Delta\Psi\text{m}$ is linked to caspase activity by initiating the cyt c release resulting in apoptosis¹⁰⁹. After endocytic uptake of nanoparticles (e.g., ZnO NP), they interact with lysosomes and may impair their formation and function^{110–112}. Lysosomes contain hydrolases that degrade different cellular macromolecules¹¹³. Lysosomal overload followed by cellular generation of ROS may lead to a collapse of lysosomal membrane permeabilization (LMP). *Yuan et al. (2002)* asserted that the induction of apoptosis by primary lysosomal destabilization is p53 dependent¹¹⁴. *Cho et al. (2011)* observed a lysosomal destabilization after treatment with metal oxide particles. They suggested that a high local ion concentration led to LMP damage which results in cell death¹¹⁵. The reaction of radicals with fatty acids leads to the generation of lipid peroxyl radicals, which put a chain reaction in motion. This possibly leads to loss of membrane integrity, release of LDH, and intracellular increase of ROS. The release of LDH was observed after treatment with ZnO NP for up to 24 h indicating the loss of membrane integrity^{116,117}. The nuclear internalization of nanoparticles is not completely understood yet, nevertheless some investigators refer to a nuclear uptake of small particles through nuclear pores via passive diffusion^{118–120}. *Panté et al. (2002)* suggested that

nanoparticles (> 39 nm) interact with specific transport receptors to enter the nuclear envelope¹¹⁹.

1.3.3.1 Programmed cell death induced by nanoparticles

Exposure to nanoparticles may lead to cellular damages resulting in apoptosis or necrosis. Apoptosis is a normal physiological process during development. Additionally, for cells with intolerant amounts of DNA damages, the apoptosis is activated by DDR¹²¹. The complex process of apoptosis is expired through at least two pathways, the extrinsic and the intrinsic pathway¹²². The activation of the extrinsic signal cascade occurs by receptors of the tumor necrosis factor (TNF), family binding extrinsic ligands (FasL, TNF- α), and transducing intracellular signals initiating caspase activity^{122,123}. The intrinsic apoptotic process is linked to the mitochondria^{122,124}. In presence of DNA damage, activated p53 promotes the expression of diverse pro-apoptotic genes such as Puma, Noxa or Bax of the Bcl-2 family^{104,121,125}. The activation of the pro-apoptotic signaling results in the depolarization of $\Delta\Psi_m$ ¹²⁶. The emerging permeabilization of mitochondria leads to a cyt c release into the cytosol. Cyt c and dATP bind to Apaf-1 resulting in conformation changes of the Apaf-1 protein^{127,128}. Therefore, the CARD domain of Apaf-1 protein is accessible for pro-caspase 9, which forms a complex referred to apoptosom, which then further initiates the caspase activation^{104,121,127,128,129}. The exposition with nanoparticles can result in apoptosis through the intrinsic and extrinsic pathways. Reactive nitrogen species (RNS) can directly activate the extrinsic pathway through the Fas death receptor¹³⁰. *Akhtar et al. (2012)* observed a ROS mediated activation of the intrinsic pathway through p53 after exposure to ZnO NP¹³¹. Furthermore, an induction of TNF- α expression via ROS-Erk-Egr-1 pathway activation was observed in keratinocytes after ZnO NP treatment¹³². The Raf/MEK/Erk pathway directly interacts with the Ras/PI3K/PTEN/Akt pathway regulating cellular growth, apoptosis and tumorigenesis¹³³. Erk1/2 regulates apoptosis by posttranslational phosphorylation of pro-apoptotic proteins¹³⁴. *Persons et al. (2000)* reported a function of Erk1/2 in DNA damage response which leads to stabilization of p53¹³⁵. *Tang et al. (2002)* showed as well that Erk1/2 interacts with p53, resulting in cell cycle arrest or apoptosis¹³⁶. Both pathways interact with p53 and may lead to an alteration of the subcellular localization and activity of pro-apoptotic proteins (e.g., Puma and Noxa)¹³³. ZnO NP are able to initiate the activation of p53-signaling¹³⁷. *Meyer et al. (2011)* showed that ZnO NP treatment of human dermal fibroblasts lead to a reduced sensitivity to ZnO NP induced apoptosis in p53-knock out cells¹³⁷. *Wilhelmi et al. (2013)* showed the induction of apoptosis as well as necrosis in

macrophages after ZnO NP exposure¹³⁸. Besides, the ZnO NP may directly induce mitochondrial impairments or DNA damages.

1.3.4 Nanoparticle induced genotoxicity

Various physical and chemical environmental agents (e.g., ionizing radiation, UV light, genotoxic chemicals) as well as by-products of physiological processes cause a diversity of DNA damages^{139–142}. Metallic nanoparticles are able to damage the DNA indirectly by inflammation and oxidative distress^{143,144}. Some DNA aberrations arise by generated ROS, from oxidative respiration, or during Fenton reactions initiated by heavy metals^{142,145,146}. Furthermore, endogenous DNA damages are induced by free radicals generated through lipid peroxidation¹⁴⁷. The particle diffusion inside the nucleus is thinkable due to their small size. Furthermore, positively charged particles may pass the nuclear envelope and possibly interact directly with the negatively charged DNA^{148,149}. The most common types of DNA lesions are single strand breaks (SSB), DSB, mismatches, and chemical adducts¹⁴¹. The most hazardous type of DNA damages are DNA DSB¹⁵⁰. SSB, generated by ROS, could be converted to DSB in case of two proximate SSB or if the DNA replication encounters SSB during S phase of the cell cycle^{142,151,152}. *Hackenberg et al. (2011)* showed that a repetitive exposure of human nasal mucosa cells treated with ZnO NP leads to DNA damages⁷¹. Gold NP are known to interfere with DNA repair proteins such as BRCA1 or induce the expression of genes involved in cell cycle arrest or induction of apoptosis¹⁵³. The types of DNA damage as well as the mechanism of these genotoxicity are not well established. DNA damages may lead to apoptosis or mutagenicity mediated directly by metal oxide NP or indirectly through their dissociated ions¹⁵⁴.

1.3.4.1 DNA damage response

The cellular response to DNA lesions is attended by a diversity of cell cycle checkpoints and activates several DNA repair pathways¹³⁹. One of the first steps of DNA damage response (DDR) is the recognition of DNA damages initiating the phosphorylation of histone H2A.X. *Rogakou et al. (1998)* showed that H2A.X can be phosphorylated on Ser 1, ubiquitinated on Lys 119 and acetylated on Lys 5. The rapidly phosphorylation of Ser 139 occurs in presence of DNA DSB which makes the difference to other H2A family members¹⁵⁵. The phosphorylation of Serine on position 139 is termed γ H2A.X¹⁵⁵. This phosphorylation is induced in response to DNA DSB, affected by exogenous agents, replication stress or apoptosis^{155–158}. For the first time *Sedelnikova et al. (2002)*

1 Introduction

described γ H2A.X as specific DNA DSB marker, because of its fast induction and amplification around the DSB¹⁵⁹. γ H2A.X is dephosphorylated by the phosphatase called PP2A after DNA damage repair¹⁶⁰. Main sensors of the DDR are ataxia telangiectasia mutated (ATM) and ataxia telangiectasia and Rad3-related (ATR), which are activated and recruited to the DNA DSB and replication protein A (RPA)-coated ssDNA, respectively^{139,161–163}. ATM and ATR are members of the PIKK family which specifically phosphorylate serine and threonine residues of proteins^{139,142}. ATM is mainly activated in presence of DSB, while ATR is activated in response to inhibit DNA replication forks or SSB¹⁶⁴. The two best studied downstream targets of ATR and ATM are the effector kinases Chk1 and Chk2. ATR activates Chk1, whereas ATM activates Chk2^{165,166}. Both sensors as well as their effector kinases reduce the activity of cyclin-dependent kinase (CDK) through different mechanisms, e.g., by stabilization of p53 in order to inhibit the cell cycle, promote DNA repair or initiate pro-/anti-survival signaling cascades^{148,165,167–169,164}. The activation of DDR mobilizes DDR proteins to the site of damage initiating the damage repair¹⁷⁰.

Figure 6: DNA damage response signaling

H2A.X is phosphorylated in presence of DNA damage. The DNA DSB is recognized by the MRN complex and resulting in the activation of ATM. In response to ATM phosphorylation different DDR proteins are recruited to the site of DNA damage. Furthermore, ATM activates a variety of downstream substrates such as Chk2, p53, MDM2 and MDM4. DNA SSB become coated with the RPA protein recruiting the ATR-ATRIP complex. This complex activates the 9-1-1 complex, which in turn activates ATR. Phosphorylated ATR activates their downstream proteins Chk1, p53, MDM2 and MDM4 (adapted from:¹⁷¹).

1.3.4.2 P53, the guardian of the genome

In response to DNA damage, both ATR-Chk1 as well as ATM-Chk2, induce a range of posttranslational modifications on p53, leading to cell cycle arrest and damage repair or apoptosis for instance^{171,172}. In this context, the p53 is one of the main effectors of DDR. P53 is an unstable transcription factor which becomes phosphorylated and stabilized in response to cellular stresses, particularly in presence of DNA damages^{173–175}. The activity of p53 is regulated by diverse posttranscriptional and posttranslational modifications such as alternative splicing, phosphorylation and conformational changes¹⁷⁶. The release of p53 from its negative regulator, mouse double minute 2 (MDM2) and mouse double minute 4 (MDM4), is the key step of p53 stabilization and connected to a feedback transcriptional regulation of MDM2^{156,171,172,176}. Under normal physiological conditions, p53 is present in an instable form ($t_{1/2} \sim 30$ min) and becomes ubiquitylated and proteasomal degraded by E3 ubiquitin ligases or MDM2^{171,176,177}. The adapter protein DAXX interacts with the herpesvirus-associated ubiquitin-specific protease (HAUSP) and the MDM2^{171,178}. This interaction reduces the auto-ubiquitylation activity of MDM2 and further enhances the degradation and turnover of p53¹⁷¹. The induction of ATM and ATR during genotoxic cellular stresses induces a wide range of p53 modification, resulting in MDM2-DAXX-HAUSP complex disruption and ubiquitylation of MDM2 and MDM4¹⁷¹. Two well investigated main consequences of p53 stabilization initiated by DNA damage are the cell cycle arrest with induction of DNA repair and apoptosis.

Figure 7: Degradation and stabilization of p53

Under physiological conditions p53 is proteasomal degraded after ubiquitylation. The ubiquitylation of p53 is mediated by the marking of MDM2 and MDM4. The effort of p53 could be enhanced by several proteins such as DAXX and HAUSP, which deubiquitylate MDM2 and MDM4. The activation of DDR by ATM or ATR leads to induction of p53 through MDM2-DAXX-HAUSP complex rupture and disruption of MDM2 and MDM4 (adapted from:¹⁷¹).

1.3.4.3 Repair of DNA DSB

The two major DSB repair mechanisms are the homologous recombination (HR) and non-homologous end-joining (NHEJ). The NHEJ is active during the whole cell cycle (preferred repair mode G1 and S phase) linking the break end directly and does not need the homologous template for repair^{179–182}. Therefore, the Ku heterodimer (Ku70 and Ku80) binds to the ends of DNA DSB, brings the catalytic subunit of DNA PK and the Ligase4-XRCC4 to complete NHEJ¹⁸³. DNA DSB can occur during S phase because of replication stress and replication fork collapse. Furthermore, the CDK activity during S phase is low affecting the initiation of HR¹⁸³. The HR uses the intact sister chromatid as a template for DNA DSB repair and is therefore restricted to the late S and G2 phase^{165,166,180,181,182,184}. The activation of the checkpoint control and the repair of DNA DSB, by NHEJ and HR, are important for cell cycle progression and cellular survival.

1.3.5 Possible damaging potential of dissociated Zn²⁺

Another toxic mechanism of metallic nanoparticles is postulated as Zn²⁺ mediated by particle dissociation¹⁸⁵. Changes of particle surface constitutions (i.e., using iron doping or BSA coating) reduces ion release from particles and this resulted in reduced toxic cellular effects^{186,187}. Furthermore it is a question of debate in which cellular environment the ZnO NP dissociate. ZnO is often classified in material safety data sheets as insoluble in H₂O, while others reported a highly pH-dependent solubility of ZnO^{188,189}. *Muller et al. (2010)* observed a pH-dependent solubility of ZnO NP and therefore reinforced toxicity. They observed particle dissociation in acidic environment suggesting the release of Zn²⁺ after endocytic uptake in endosomal vesicles¹¹². In many physiological processes zinc plays an essential role as functional, structural, and regulatory element. Due to this importance a potential toxicity derives from the disturbance of zinc homeostasis. The homeostasis and steady state concentrations of free intracellular Zn²⁺ are maintained by buffering systems. Therefore, the intracellular free Zn²⁺ concentration has to be tightly controlled. The involvement of deregulated Zn²⁺ homeostasis is well known for type 2 diabetes and more recently the proper regulation of the sub-cellular distribution has been shown to be relevant. Eukaryotic cells contain much more zinc than other transition metals and need to distribute them to many proteins to guarantee their functional activity¹⁹⁰. The metal-response-element-binding transcription factor (MTF-1) plays a substantial role in the control of zinc homeostasis. MTF-1 serves as sensor of high levels of intracellular free Zn²⁺ and induces the transcription of MT. Low changes of the intracellular steady state Zn²⁺ concentration can be corrected by MT which is known as

regulator in buffering. ROS may lead to an increased Zn^{2+} concentration caused by the oxidation of thiol groups of the zinc-binding proteins resulting in reduced buffer capacity which leads to toxicity¹⁹⁰. The second regulation mechanism of intracellular Zn^{2+} , named muffeling reaction, is organized by several zinc binding proteins and transporters distributing the free Zn^{2+} into compartments or external secretion¹⁹⁰. It is quite important that Zn^{2+} has no uncontrolled access to metalloproteins, because the binding of metals to proteins follows the series of Irving-Williams showing that Zn^{2+} is highly preferred over most other metals^{191,192}. *Peck et al. (1971)* investigated in the enzyme activity of phosphoglucomutases in rabbits and observed that high intracellular concentrations of free Zn^{2+} resulted in a reduced enzyme activity, because Zn^{2+} is able to displace Mg^{2+} as cofactor¹⁹². Zn^{2+} imbalance between mitochondria and cytoplasm, e.g., might result in insulin resistance and cell damage by induction of apoptosis¹⁹³. The human genome encodes more than 3000 proteins comprising zinc. Due to its binding affinity to thousands of proteins, Zn^{2+} is crucial for cells differentiation, proliferation, signaling, and survival^{176,190,191,194}. The functional Zn^{2+} is mostly located as catalytical unit in several enzyme classes such as ligases, hydrolases, and transferases as well as in different secretory enzymes¹⁹⁵. Zinc, as a catalytical component, is located at the active site through four ligands (e.g., histidine, cysteine, aspartic- and glutamic acid)¹⁹⁴. Furthermore, zinc is described as modulating coactivator together with copper (e.g., superoxide dismutases)¹⁹⁶. Zinc acts also in a structural way by binding to amino acid side chains to stabilize the active tertiary structure of proteins (e.g., alcohol dehydrogenase). It serves also in histones, as DNA structure stabilizing component (e.g., histone deacetylases), which carry Zn^{2+} in their active center¹⁹⁷. The functional integrity of these enzymes is substantial for proper epigenetic regulation of gene expression. Zinc is an element of transcriptionfactors and plays therefore a critical part in the regulation of DNA transcription and replication. Zinc is an essential element of zinc finger and many proteins involved in DNA repair (e.g., XPA, PARP, and Fpg). Zn^{2+} is able to cause activity loss of PARP-1 and OGG1 in subcellular systems^{198,199}. Furthermore, it was shown that zinc acts as DNA repair inhibitor in presence of oxidative caused DNA base modifications¹⁹⁸. The activity of DNA mismatch repair depends on a conserved Zn-binding domain of the hPMS2 subunit of the MutLalpha heterodimer. These important proteins are of great significance for maintaining DNA integrity and genomic stability. They are also associated with the hereditary form of colon cancer in case of their inactivation²⁰⁰. Zinc is essential for intra- and intercellular communication. Thus, there is evidence that Zn^{2+} serves as an intracellular signaling molecule, similar as known for Ca^{2+} ^{201,202}. Free Zn^{2+} is involved in neurotransmitter functions mediating intercellular communication and acting as an intracellular signaling molecule.

1 Introduction

Yamashita et al. (2004) showed that the zinc transporter LIV1 is essential for the nuclear translocation of the Zn-finger transcription factor Snail, a master regulator of epithelial-mesenchymal transition (EMT)²⁰³. EMT is a key event of tissue development and cancer progression. Another function of nuclear Zn²⁺ is its participation in pre-mRNA splicing as a cofactor in spliceosomes^{204,205}.

Dissociation of ZnO NP into Zn²⁺ is a possible toxic mechanism of metallic oxide particle. All these many examples underscore a relevant role for Zn²⁺ in nuclear functions and consequences in the case of dysregulated sub-cellular homeostasis.

2 Aims of this work

Metal and metal oxide nanoparticles are commonly used as additives in industrial production of rubbers, catalysts, foods, pharmaceuticals and cosmetics. Prospectively, a continuous rise of industrial application is estimated, which results in an increasing release to environment and humans' exposure. Therefore, it is of importance to investigate potential adverse effects. Metallic nanoparticle intake of humans' results in inflammatory reactions known as *metal fume fever* and a multitude of publications report toxic effects in cell culture and animals. More recently genotoxic effects have been suggested to be associated with metal oxide nanoparticle intake. In this study ZnO NP were used as a model of metal oxide nanoparticles to evaluate mechanisms of genotoxicity in respiratory epithelia. The study aimed to investigate the intracellular ZnO NP uptake and distribution, their toxicity, DNA damaging potential, and DNA damage response (DDR) activation.

In particular the following questions were targeted:

- How are ZnO NP internalized by the cell and where are they accumulated?
- Is there a size dependent effect in cellular uptake, accumulation and toxicity?
- Are ZnO NP genotoxic?
- Do they activate the DNA damage response?
- What are the mechanisms of genotoxicity?

3 Materials and methods

3.1 Materials

Table 1: Equipment

Equipment	Manufacturer
Atomic absorption spectroscopy, AAS	PerkinElmer, Waltham, MA, USA
Autoclave 5050 ELV	Tuttnauer, Breda, Netherland
BD FACS Canto II	Becton Dickinson, Francklin Lakes, NJ, USA
CASY [®] Cell counter, Model TT	Roche Diagnostics International AG, Basel, Swiss
Centrifuge, Biofuge fresco	Heraeus, Kendro Laboratory Products, Hanau, Germany
Centrifuge, Multifuge 1L-R	Heraeus, Kendro Laboratory Products, Hanau, Germany
Combs, 1.0 mm, 10 wells	Biometra GmbH, Göttingen, Germany
Micro Centrifuge Modell: 100 VAC Fisherbrand [®]	Fisher Scientific, Schwerte, Germany
ChemiDoc MP system	Bio-Rad Laboratories, Inc., Hercules, CA, USA
cLSM Leica TCS SP5	Leica Camera, Solms, Germany
Digital camera	VDS Vosskühler GmbH CCD-1300, Osnabrück, Germany
Electrophoresis Chamber	Biometra GmbH, Göttingen, Germany
Fastblot B43Semi-Dry Blotter Trans-Blot [®] SD	Biometra GmbH, Göttingen, Germany
FluoroMax 2	Horiba Seisakusho, Kyōto, Japan
Fluoroskan Ascent [™] Microplate	Thermo Fisher Scientific GmbH, Rockford, USA
Freezer (-20°C), Liebherr Premium	Liebherr, Bulle, Switzerland
Glass plates with fixed 1.0 mm spacers	Biometra GmbH, Göttingen, Germany
Hemocytometer	Paul Marienfeld GmbH & Co. KG, Lauda-Königshofen, Germany
Hera Freezer (-80°C)	Kendro Laboratory Products, Hanau, Germany
Incubator, Heracell 150i CO ₂ Incubators	Thermo Scientific, Waltham, MA, USA
Irradiation equipment, Gammacell 2000, γ-source (Cs137) source	Mølgaard Medical, Risø, Denmark
Laminar flow cabinet, Herasafe Safety cabinets	Heraeus, Kendro Laboratory Products, Hanau, Germany
Magnetic stirrer, MR3001	Heidolph, Schwabach, Germany
Magnetic stirrer, Heidolph MR 3001	VWR international, Darmstadt, Germany
Microscope, Leitz Orthoplan	Leica, Wetzlar, Germany
Microscope, Nikon TMS	Nikon, Düsseldorf, Germany
Microscope fluorescence, Nikon Eclipse TE2000U	Nikon, Düsseldorf, Germany
Minicentrifuge RF	Heraeus, Kendro Laboratory Products, Hanau, Germany
Minicentrifuge Universal 16 R	Hettich Zentrifugen, Tuttlingen, Germany
Nitrogen tank	CRYO-4000, Chart Ind., Burnsville, MN, USA
Pipette	Eppendorf AG, Hamburg, Germany
Pipetus [®]	Hirschmann Laborgeräte, Eberstadt, Germany
Power Supply, Modell 1000/500 Constant voltage	BioRad, Hercules, CA, USA
Power Supply, Standard power pack P25	Biometra GmbH, Göttingen, Germany
Refrigerator profi line	Liebherr, Bulle, Switzerland
Rocking platform shaker WS-10	Edmund Bühler, Hechingen, Germany
Running rig Midigel + Twin G42	Biometra GmbH, Göttingen, Germany
Scale Kern PCB	Kern und Sohn GmbH, Balingen Frommern, Germany

Analysis of ZnO NP as a potential mutagen of respiratory epithelia

Scale Precision Advanced DHAUS	As-Wägetechnik GmbH, Garching, Germany
Scanner, Epson Perfection 3200 Photo	Epson, Meerbusch, Germany
Semi-dry electrophoretic transfer cell	Biometra GmbH, Göttingen, Germany
Shaker, Rotor WS-10	Edmund Bühler, Hechingen, Germany
Shaker, Rocky 3D	Labortechnik Fröbel GmbH, Lindau, Germany
Silicone rubber seal, 1.0 mm	Biometra GmbH, Göttingen, Germany
Sonorex Super RK 510 H	Bandelin electronic GmbH & Co. KG, Berlin, Germany
Spectrophotometer Fluoroskan Ascent Microplate	Thermo Electron Corporation, Dreieich, Germany
StripHolder	Labcrew, Amersham Bioscience, Sunnyvale, CA, USA
Thermomixer, HLC-TM 130-6	Haep Labor Consult, Bovenden, Germany
Thermomixer comfort	Eppendorf AG, Hamburg, Germany
Transferpette® S	Brand GmbH & Co KG, Wertheim, Germany
TEM Philips EM420	Koninklijke Philips N. V., Amsterdam, Netherlands
TEM Leo 906	Carl Zeiss AG, Oberkochen, Germany
Teflon-lined stainless steel autoclave	Institute of inorganic and analytical chemistry, JGU, Mainz
Ultracut 41	Reichert-Jung, Vienna, Austria
Ultrasonic homogenisers, LABSONIC M	B. Braun Biotech International, Melsungen, Germany
Vacuum rotary evaporator	BÜCHI Labortechnik AG, Essen, Germany
Vortex, Top-Mix 11118 Fisherbrand®	Fisher Scientific, Schwerte, Germany
Vortex, VV3	VWR International, Radnor, PA, USA
Water bath	INFORS HT, Bottmingen, Swiss
Zetasizer Nano ZS	Malvern Instruments, Malvern, UK

Table 2: Chemicals

Chemicals	Manufacturer
Acetic acid	AppliChem, Inc., St. Louis, MO, USA
AlamarBlue®	BIOZOL Diagnostica Vertrieb GmbH, Eching, Germany
Ammonium acetate	Sigma-Aldrich, St. Louis, MO, USA
Albumin Fraction V, BSA	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Aprotinin	Sigma-Aldrich, St. Louis, MO, USA
Bromophenol blue	Sigma-Aldrich, St. Louis, MO, USA
Calcium chloride, CaCl ₂	MERCK MILLIPORE, Merck KGaA, Darmstadt, Germany
Carbonyl cyanide 3-chlorophenylhydrazone, CCCP	Sigma-Aldrich, St. Louis, MO, USA
CellLight® Early Endosomes-RFP	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Casy® toner	Roche Diagnostics International AG, Basel, Swiss
Crystal violet solution	Sigma-Aldrich, St. Louis, MO, USA
Cy5	Abcam, Cambridge, UK
3,3'-Diaminobenzidine, DAB	DAKO Deutschland GmbH, Hamburg, Germany
Dimethylsulfoxid, DMSO	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Diethylene triamine pentaacetic acid, DTPA	FLUKA, Sigma-Aldrich, St. Louis, MO, USA
Dithiothreitol, DTT	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Disodium phosphate, Na ₂ HPO ₄	Sigma-Aldrich, St. Louis, MO, USA
Western Lightning Plus ECL	PerkinElmer, Waltham, MA, USA

3 Materials and methods

ER-Tracker™ Red (BODIPY® TR, glibenclamide)	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Ethylenediaminetetraacetic acid, EDTA	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Epidermal growth factor, human, EGF	Sigma-Aldrich, St. Louis, MO, USA
Ethanol, EtOH	AppliChem, Inc., St. Louis, MO, USA
FITC Annexin V	BioLegend Inc., San Diego, CA, USA
Fluorescence Mounting Medium	DAKO Deutschland GmbH, Hamburg, Germany
FluoZin™-3, AM, cell permeant	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Glutaraldehyde	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Glycine	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Glycerol	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
β-Glycerophosphate	Sigma-Aldrich, St. Louis, MO, USA
4-(2-Hydroxyethyl)piperazine-1-ethanesulfonic acid, HEPES	Sigma-Aldrich, St. Louis, MO, USA
2',7'-dichlorodihydrofluorescein diacetate, H ₂ DFCDA	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Hexane	AppliChem, Inc., St. Louis, MO, USA
Heat inactivated FCS	Sigma-Aldrich, St. Louis, MO, USA
High purity H ₂ O	Cayman Chemical Company, Ann Arbor, MI, USA
Hydrogen chloride	Sigma-Aldrich, St. Louis, MO, USA
Hydrogen peroxide (H ₂ O ₂)	Sigma-Aldrich, St. Louis, MO, USA
Hämalaun solution	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Hydrocortisone	Sigma-Aldrich, St. Louis, MO, USA
Insulin	Sigma-Aldrich, St. Louis, MO, USA
Isopropyl alcohol	AppliChem, Inc., St. Louis, MO, USA
5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolocarbo-cyanine iodide, JC-1 dye	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Leupeptin	Sigma-Aldrich, St. Louis, MO, USA
LR-white™	London Resin, London, UK
Methanol	AppliChem, Inc., St. Louis, MO, USA
MitoTracker® Deep Red FM	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Monopotassium phosphate, KH ₂ PO ₄	Sigma-Aldrich, St. Louis, MO, USA
N-acetyl-L-cysteine, NAC	Sigma-Aldrich, St. Louis, MO, USA
Paraformaldehyde, PFA	Sigma-Aldrich, St. Louis, MO, USA
PageRuler™ Prestained Protein Ladder	Thermo Scientific™, Carlsbad, CA, USA
Pepstatin	Sigma-Aldrich, St. Louis, MO, USA
Phosphate-buffered saline, PBS	Sigma-Aldrich, St. Louis, MO, USA
Propidium Iodide, PI	Abcam, Cambridge, UK
Picric acid	Riedel-de Haën, Sigma-Aldrich, St. Louis, MO, USA
Pluronic® F-127	Molecular Probes®, life technologies™, Carlsbad, CA, USA
Powdered milk	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Retinol	Sigma-Aldrich, St. Louis, MO, USA
Sodium dodecyl sulfate, SDS	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Sodium chloride, NaCl	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Sodium lauroyl sarcosinate	Sigma-Aldrich, St. Louis, MO, USA
Sodium azide, NaN ₃	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Sodium acetate	Sigma-Aldrich, St. Louis, MO, USA
Sodium fluoride, NaF	Sigma-Aldrich, St. Louis, MO, USA

Analysis of ZnO NP as a potential mutagen of respiratory epithelia

Sterillium® classic pure	Bode Chemie GmbH, Hamburg, Germany
Streptavidin/HRP	DAKO Deutschland GmbH, Hamburg, Germany
SYBR® Green	Applied Biosystems®, life technologies™, Carlsbad, CA, USA
Tocopherols	Sigma-Aldrich, St. Louis, MO, USA
TRIS buffered saline, TBS	Sigma-Aldrich, St. Louis, MO, USA
Tetramethylammonium hydroxide	Sigma-Aldrich, St. Louis, MO, USA
3,3',5,5'-Tetramethylbenzidine	Sigma-Aldrich, St. Louis, MO, USA
Transferrin	Sigma-Aldrich, St. Louis, MO, USA
Tris(hydroxymethyl)-aminomethane, TRIS	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Triton X-100	Sigma-Aldrich, St. Louis, MO, USA
Trypan Blue	Sigma-Aldrich, St. Louis, MO, USA
Tween ₂₀	Carl Roth GmbH & Co. KG, Karlsruhe, Germany
Vectashield® Hard+Set™	Vector Laboratories, Inc., Burlingame, CA, USA
Zinc chloride	Sigma-Aldrich, St. Louis, MO, USA

Table 3: Consumables

Consumables	Manufacturer
Advanced TC Dish, Sterile, 60 x 15 mm	Greiner Bio-One GmbH, Frickenhausen, Germany
BD Falcon™ cell scraper	BD Biosciences, Bedford, UK
Blotting paper	MACHEREY-NAGEL GmbH & Co. KG, Düren, Germany
Cell culture dishes cellstar® 96 well plate, black, 15MM REF 655090 µCLEAR®	Greiner Bio-One GmbH, Frickenhausen, Germany
ibiTreat, sterile, µ-Dish 35 mm, high	ibidi GmbH, Martinsried, Munich, Germany
TEM grids made of copper coated with carbon film	Plano GmbH, Wetzlar, Germany
ELISA microplate	Corning, Inc., Corning, NY, USA
Cell culture flask; 175 cm ² , 75 cm ² , 25 cm ²	Cellstar, Greiner, Frickenhausen, Germany
Microscope Cover Slip, 18x18 mm	IDL GmbH & Co KG, Nidderau, Germany
Microscope Cover Slip, ø10 mm	Gerhard Menzel GmbH, Braunschweig, Germany
Cryo tubes, Cryo. S™	Greiner Bio-One GmbH, Frickenhausen, Germany
Tubes, cellstar® tubes; 15 mL, 50 mL	Greiner Bio-One GmbH, Frickenhausen, Germany

3.2 Methods

3.2.1 Synthesis of ZnO nanoparticles

The ZnO NP were synthesized by the [REDACTED]. Two different sizes of ZnO NP (4-5 nm and 15-18 nm) were used in this study. ZnO NP in a size of 15-18 nm were synthesized with slight modifications, following a procedure reported by *Cheng et al. (2006)*²⁰⁶. $\text{Zn}(\text{Ac})_2 \times 2 \text{H}_2\text{O}$ (1.09 g) was dissolved in 10 mL of methanol. Tetramethylammonium hydroxide (25 % w/w) in water and tetramethyl-ammonium hydroxide (25 % w/w in methanol) were added in a ratio of 1 to 3 (total volume of 20 mL) under stirring conditions at RT. The solution was transferred to a teflon-lined stainless steel autoclave and heated to 50°C for 24 h. The white precipitate was collected and purified by washing with high purity H_2O and dried afterwards at RT. ZnO NP in a size of 4-5 nm were synthesized using a procedure developed and reported by *Tahir et al. (2009)*²⁰⁷. A batch of ZnO colloids was synthesized by dissolving 110 mg (0.5 mM) of $\text{Zn}(\text{AC})_2 \times 2 \text{H}_2\text{O}$ in 25 mL of ethanol (EtOH) with sonication at 0°C for 15 min. 21 mg (0.5 mM) of $\text{Li}(\text{OH}) \times \text{H}_2\text{O}$ were added to ZnO colloid solution and sonicated at 0°C for 15 min. The solvent of the obtained stable and optically transparent ZnO solution was removed using a vacuum rotary evaporator. Then ZnO NP were redispersed in high purity H_2O and dialysed against H_2O to remove excess of base $\text{Li}(\text{OH})$.

3.2.2 Analytical characterization of ZnO NP

The particles were characterized by transmission electron microscopy (TEM), ζ -potential and atomic absorption spectroscopy (AAS).

3.2.2.1 Transmission electron microscopy

The size and shape of the ZnO NP were determined using TEM with an acceleration voltage of 120 kV. Samples were prepared by dropping ZnO NP in high purity H_2O on a TEM grid.

3.2.2.2 ζ -potential measurement

Nanoparticles possess a specific positive or negative electrostatic charge with influence on cellular particle uptake. The measurement of the ζ -potential of the ZnO NP was

3 Materials and methods

performed using a Zetasizer. The ZnO NP dispersion was applied to a disposable capillary cell and the particles migrated in the applied electrical field. 1 mL aliquots of each sample were injected into the capillary cell and 5–10 measurement per sample were performed at 25°C.

3.2.2.3 Atomic absorption spectroscopy

The atomic absorption spectroscopy (AAS) is a spectroanalytical method using the absorption of light by free atoms in the state of gas to quantify chemical elements (e.g., Zn). ZnO NP (4-5 nm, 15-18 nm) were prepared in high purity H₂O (pH 5.8) or in cell culture medium (pH 7.4) as mentioned below (see 3.2.4.1). A 50 mL tube was filled with 35 mL of high purity H₂O and another with 35 mL cell culture medium. ZnO NP were diluted in high purity H₂O to a final concentration of 100 µg/mL. 5 mL of each tube were transferred to another tube and centrifuged at 12,000xg for 5 min. 4 mL of the supernatants were transferred to a wetted glass after 1 min, 5 min, 15 min, 30 min, 1 h and 4 h. Solutions were stored at RT on a rocking platform shaker until analysis. The dissociated Zn were measured using AAS at the [REDACTED].

3.2.3 Cell culture

3.2.3.1 Cell lines and conditions

Three different cell lines and primary cells of mucosa were used. A549 is an adenocarcinomic human alveolar epithelial-like type-II cell line that has been established in 1979 after removal of cancerous lung tissue of a 58 years old Caucasian male. NIH/3T3 cells have been established in 1962 from swiss albino mouse embryo tissue and are used as standard model for fibroblasts. HNSCCUM-02T is a human squamous cell carcinoma cell line from the base of the tongue, which has been established 2003 from *Welkoborsky et al. (2003)* in the lab of the [REDACTED].

[REDACTED]²⁰⁸. The primary cells of mucosa were isolated from the gingiva of patients operated at the [REDACTED].

[REDACTED] and cultivated at the [REDACTED].

The cells were maintained in cell culture medium using *Dulbecco's Modified Eagles's Medium* (DMEM), supplemented with 5 % fetal calf serum (FCS) and 1 % penicillin/streptomycin (P/S). All used cell lines were cultivated at 37°C, 5 % CO₂, and

humidified atmosphere. For detailed cultivation conditions of cell lines please refer to 3.2.3.2 and for primary cells of mucosa 3.2.3.5, and 3.2.3.6.

3.2.3.2 Cell line cultivation

The culture medium was replaced every second day. After confluence of 80 %, cells were splitted for further cultivation. For passaging of A549, NIH/3T3, and HNSCCUM-02T cells, Trypsin/EDTA (T/E) was used (1:10 dilution). The confluent cells were rinsed with phosphate-buffered saline (PBS) and 2 mL of the ready to use mixture of T/E was added and incubated at 37°C until the cells were detached. Cells were transferred to a 15 mL tube and culture medium was added in a 1:1 ratio. Afterwards, cells were centrifuged at 300xg for 5 min. Supernatant was discarded and the cell pellet resuspended in 5 mL cell culture medium. In order to determine the cell amount, 20 µL of the cell suspension was mixed with 20 µL of trypan blue (1:1 ratio) and counted in a hemacytometer. The cells were systematically counted under a microscope. The total number of viable cells in the prepared cell suspension was calculated using the following formula:

$$\text{Total number of viable cells} = \left(\frac{A}{B} \right) \times C \times D \times E$$

Formula 1: Calculation of total cell counts

A: viable cells; B: number of squares; C: dilution factor (2); D: volume of cell suspension; E: chamber factor (10,000)

3.2.3.3 Viability measurement with CASY TT®

Viability was measured by the use of CASY TT®, an electric field multi-channel cell counting system. CASY TT® measures cell amount, cell size and cell viability and is based on a pulse surface analysis. The cells were sucked with a constant speed into a capillary between two electrodes. The magneto-resistance of the capillary equates to the cell volume. The cell membrane of a dead or injured cell is more permeable than those of an intact cell and causes less change in magneto-resistance. The cells were treated with 100 µg/mL ZnO NP. The cellular viability of the cells was determined after 24 h of ZnO NP exposure or BSA stabilized ZnO NP (see 3.2.4). After incubation cells were trypsinized and centrifuged at 450xg for 8 min. The cells were resuspended with 750 µL cell culture medium. Afterwards, 4 tubes with 10 mL of CASY-toner were supplied with 200 µL (50:1) cell suspension of each time point and were measured by CASY TT®.

3.2.3.4 Freezing and thawing procedure of cells

Freezing: The cells were washed with PBS and detached from cell culture flask as mentioned above (see 3.2.3.2). After detaching, cells were centrifuged and the supernatant was replaced by FCS containing 10 % dimethyl sulfoxide (DMSO). The cell pellet was resuspended and 1 mL (approx. 1×10^6 cells) was transferred to cryo tubes. Then, the cryo tubes were stored at -80°C overnight and finally transferred into liquefied nitrogen.

Thawing: Frozen cells, were thawed in a 37°C tempered water bath and resuspended in prewarmed fresh cell culture medium. Afterwards, cells were centrifuged at $300 \times g$ and the pellet was resuspended in fresh cell culture medium before the cells were cultivated at 37°C and 5 % CO_2 .

3.2.3.5 Isolation of primary cells of mucosa from gingiva

Before starting with cell isolation the fresh mucosa tissue was sliced for 1 min each in 70 % EtOH, Sterillium[®] classic pure and again in EtOH. First, the connective tissue was separated from the epithelial layer by cutting at the line between red (connecting tissue) and white (epithelial layer) tissue. Afterwards, the fresh tissue pieces were transferred with the epithelial layer up into a 6-well plate and covered with 1 mL of FAD complete medium.

3.2.3.6 Cultivation of primary cells of mucosa

After 24 h, the FAD complete medium of the epithelial cells was replaced by CnT-Prime medium (specialized medium for epithelial cells). The tissue was incubated and cultivated at 37°C and 5 % CO_2 until epithelial cells covered 70 % of the well. Then, the medium was discarded and the cells were incubated with T/E for 5 min. Afterwards, the cells were transferred to a tube with DMEM and a trypsin inhibitor (DTI) was added at RT for 5 min to neutralize the T/E reaction. The cell suspension was centrifuged at $300 \times g$ for 5 min. Supernatant was removed and the pellet was resuspended in cell culture medium and counted as mentioned in 3.2.3.2 and afterwards prepared for further experiments.

3.2.4 Pretreatments and treatments with ZnO NP, ZnO bulk, and ZnCl₂

3.2.4.1 Preparation of ZnO NP, ZnO bulk, and ZnCl₂ dispersion

The synthesized ZnO NP, ZnO bulk material or ZnCl₂ were weighted on the day of experiment and suspended in high purity H₂O to get a stock concentration of 1 mg/mL. The ZnO NP, ZnO bulk dispersions, and ZnCl₂ solutions were sonicated using an ultrasonic homogeniser for 5 min at 32 W. The cells were treated immediately with a final concentration of 0.1 µg/mL, 10 µg/mL or 100 µg/mL. The concentrations were chosen according to values measured in sun protection (up to 100 mg/mL²⁰⁹) and drinking water (10 µg/mL²¹⁰) of daily used products.

3.2.4.2 Pretreatment with DTPA

Diethylene triamine pentaacetic acid (DTPA) was used as a chelator of Zn²⁺, released from extracellular dissociated ZnO NP. Cells were seeded in 6-well plates and incubated at 37°C and 5 % CO₂ for 24 h. The next day, cells were pretreated with 0.06 mM DTPA for 1 h before ZnO NP were added (see 3.2.4.1).

3.2.4.3 Pretreatment with NAC

N-acetyl-L-cysteine (NAC) was used to scavenge reactive oxygen species (ROS). After seeding, the cells were incubated at 37°C and 5 % CO₂ for 24 h. The culture medium was replaced with fresh cell culture medium containing 5 mM NAC. After another 24 h of incubation the cells were incubated with cell culture medium containing NAC (5 mM) and ZnO NP in a final concentration of 100 µg/mL (see 3.2.4.1).

3.2.4.4 Stabilization of ZnO NP with BSA

Bovine serum albumin (BSA) was used for ZnO NP stabilization. A stock solution of BSA (5 mg/mL) in high purity H₂O was prepared. 20 mg of ZnO NP were weighted and incubated in 1 mL of a BSA stock solution at 4°C for 1 h. After incubation, the dispersion was sonicated using an ultrasonic homogeniser at 32 W for 5 min. Afterwards, the ZnO NP dispersion was centrifuged at 12,000xg for 10 min and the supernatant was replaced by high purity H₂O. This step was repeated three times. The BSA coated ZnO NP were used as described above (see 3.2.4.1).

3.2.4.5 Cell incubation with ZnO NP, ZnO bulk, and ZnCl₂

ZnO NP, ZnO bulk or ZnCl₂ were weighted on the day of experiment and suspended in high purity H₂O with a final concentration of 0.1, 10 or 100 µg/mL. The ZnO NP, ZnO bulk or ZnCl₂ dispersion was sonicated using an ultrasonic bath at 32 W for 5 min. The cells were treated directly with ZnO NP, ZnO bulk or ZnCl₂ for several minutes up to maximal 24 h depending on the performed assay. Further details are mentioned in the corresponding chapter.

3.2.5 Analysis of cellular ZnO NP uptake

3.2.5.1 TEM analysis of cellular ZnO NP uptake

For the ultra structural analysis of ZnO NP uptake, A549 cells were treated with ZnO NP (100 µg/mL; exposure time 1 min, 15 min, 30 min, 1 h and 4 h) and analyzed by TEM. After treatment, cells were centrifuged at 300xg for 5 min and the pellet was washed with PBS. This step was repeated three times. Afterwards, cell pellets were incubated for 15 min in fixation buffer and washed two times for 5 min in 0.1 M Sørensen buffer. Cells were dehydrated in a concentration series of ethanol (70 %, 80 %, 90 %, and 99.5 %), for 5 min, each. Afterwards, they were embedded for 10 min in a 1:1 suspension of 99.5 % ethanol and LR-White™ and further two times for 30 min in LR-White™. After embedding the pellets were then polymerised at 58°C overnight. Finally, ultrathin slides were prepared (approx. 80-100 nm) and the intracellular accumulation of ZnO NP was evaluated by TEM.

3.2.5.2 Measurement of intracellular Zn²⁺

The free intracellular Zn²⁺ concentration after ZnO NP or ZnCl₂ treatment was monitored by spectrofluorimetric analysis as well as by cLSM using a Zn²⁺ specific fluorophore, FluoZin™-3 (dissociation constant (kd) of FluoZin™-3: ~ 15 nM).

3.2.5.2.1 Cell loading with FluoZin™-3

The cells were preloaded with 1 μM (FluoZin™-3 diluted in DMSO) of the cell permeable acetoxymethoxy derivate of FluoZin™-3 in 2 mL cell culture buffer in the dark at RT for 45 min.

3.2.5.2.2 Spectrofluorimetric measurement of intracellular Zn²⁺

After 45 min of incubation, cells (approx. 1x10⁶) were washed, trypsinized, centrifuged and resuspended in 3 mL of cell culture buffer. The cell suspension was stored in the dark at RT for 30 min to allow cleavage of the acetoxymethyl (AM) ester. Afterwards, the changed intensity of FluoZin™-3 after binding to Zn²⁺ was measured by a spectrofluorometer at 494 nm (Ex) and 514 nm (Em). After 5 min of basal level measurement, ZnO NP were injected in a final concentration of 100 μg/mL. F_{max} was determined by incubation with 10 mM ZnCl₂ and F_{min} by complexation of free Zn²⁺ by the use of 100 μM EDTA. The intracellular Zn²⁺ concentration was then calculated using the following formula:

$$[\text{Zn}^{2+}] = kd \times \frac{(F - F_{\min})}{(F_{\max} - F)}$$

Formula 2: Calculation of intracellular Zn²⁺ concentration

kd: dissociation constant; F: denotes fluorescence intensity measured at a single wavelength; F_{min}: zero reference level of fluorescence;
F_{max}: maximal reference level of fluorescence.

3.2.5.2.3 Confocal laser scanning microscopy

The confocal laser scanning microscopy (cLSM) facilitates the analysis and visualization of processes in living cells. The light or fluorescence microscopy is based on parallel pixel generation, while the cLSM creates each pixel separately. The cLSM uses point illumination and the light from the focus plane is conducted to the detectors by the detector pinhole aperture. Between the detectors and the pinhole aperture resides the fluorescence barrier filter which enables the detection of different wavelength depending on the fluorophore that is linked to the analyzing sample. The biological sample became scanned from the laser beam line by line in xy-direction. The generated fluorescence was then measured with detectors (photomultipliers) pixel by pixel. With this method a sharp image at a single focal plane of a sample can be excited (see Figure 8). Advantages of cLSM in cell live imaging are the high resolution, the depth in focus, and the visualization of 3D structures. It is possible to measure simultaneous several fluorescence dyes simultaneously co-localization experiments that can be calculated quantitatively.

Figure 8: Setup of confocal laser scanning microscope

The cLSM permits 3D localization of labeled target molecules in cells. The principle of this method is described in 3.2.5.2.3. (adapted from:^{211,212}).

3.2.5.2.4 Preparation of cLSM samples

200,000 cells were seeded in an ibiTreat cell culture dish and incubated overnight at 37°C and 5 % CO₂. The cells were stained with an organelle tracker (see 3.2.5.2.5, 3.2.5.2.6, and 3.2.5.2.7) followed with the replacement of medium by 2 mL cell culture buffer including 1 µM FluoZin™-3 (see 3.2.5.2.1). After 5 min of basal level measurement, ZnO NP or ZnCl₂ were injected at a final concentration of 100 µg/mL. Afterwards, the changed intensity of FluoZin™-3 after binding to Zn²⁺ was measured and documented by cLSM over a period in time of 60 min. Fluorescence was excited at 488 nm and detected in the spectral range of 505-600 nm using hybrid detector.

3.2.5.2.5 MitoTracker® Deep Red FM

The mitochondria were labeled using MitoTracker® Deep Red FM, which contains a thiol-reactive chloromethyl moiety for specific targeting. The cells were pretreated with 500 nM MitoTracker® at 37°C and 5 % CO₂ for 45 min. After incubation, the cells were rinsed three times with cell culture buffer, prior loading with FluoZin™-3 (see 3.2.5.2.1). After further washing steps (3x 5 min) with cell culture buffer, cLSM measurement started.

Table 11: cLSM settings of FluoZin™-3 and MitoTracker® Deep Red FM

	Dye	Laser (Em)	Laser line (Ex)	Line-/Frame-average
Sequential setting 1	FluoZin™-3	PMT 2 (505 nm – 600 nm)	8 % (488)	8/1
Sequential setting 2	MitoTracker® Deep Red FM	PMT 3 (656 nm- 739 nm)	8 % (633)	

3.2.5.2.6 ER-Tracker™ Red (glibenclamide BODIPY® TR)

The endoplasmatic reticulum (ER) was stained using ER-Tracker™ Red. The dye is a drug conjugate of glibenclamide BODIPY® TR. Glibenclamide is able to bind directly to the sulphonylurea receptor of ATP-sensitive K⁺ channels localized on the ER. Cells were pretreated with 1 µM ER-Tracker™ Red at cell culture conditions for 45 min. Afterwards the cells were washed three times with cell culture buffer and loaded with FluoZin™-3 (see 3.2.5.2.1). After three washing steps for 5 min with cell culture buffer, cLSM measurement started.

3 Materials and methods

Table 12: cLSM settings of FluoZin™-3 and ER-Tracker™ Red

	Dye	Laser (Em)	Laser line (Ex)	Line-/Frame-average
Sequential setting 1	FluoZin™-3	HyD 2 (505 nm – 550 nm)	8 % (488)	8/1
Sequential setting 2	ER-Tracker™ Red	HyD 4 (587 nm - 631 nm)	8 % (561)	

3.2.5.2.7 CellLight® Reagent *BacMam 2.0* - early endosomes

The used BacMam technology avails an insect cell virus (baculovirus), which is linked to a mammalian promoter. The CellLight® reagent for early endosomes is a fluorescent protein-signal peptide regulated by a promoter fused to the Rab5a sequence targeting the early endosomes. 200,000 cells in 2 mL medium were treated with CellLight®, according to the manufacturer's data sheet. For one cell, 30 particles of the CellLight® Reagent were used. The cells were incubated with 12 µL CellLight® Reagent at 37°C and 5 % CO₂ for 20 h. Afterwards, cells were washed three times with cell culture buffer and labeled with FluoZin™-3 as mentioned before (see 3.2.5.2.1). Then the cells were washed with cell culture buffer (3x for 5 min), before cLSM measurement started. Transfection efficiencies were between 30 and 40 %.

Table 13: cLSM settings of FluoZin™-3 and CellLight® Reagent *BacMam 2.0* - early endosomes

	Dye	Laser (Em)	Laser line (Ex)	Line-/Frame-average
Sequential setting 1	FluoZin™-3	PMT 2 (500 nm – 560 nm)	5 % (488)	16/1
Sequential setting 2	CellLight® Reagent *BacMam 2.0* - early endosomes	PMT 3 (580 nm - 633 nm)	15 % (561)	

3.2.6 Flow cytometry

Flow cytometry facilitates rapid analysis of optical and fluorescence characteristics of single cells counted in a fluidic stream by a laser and electronic detection hardware. This technique provides simultaneous analysis of physical properties such as cell size and granularity as well as bound or intercalated fluorescence conjugated molecules of thousands of cells per second^{213,214}. These features are dissected using an optical-to-electronic coupling system that observed the cell scatters incident laser light and emitted fluorescence (BD Bioscience learning guide). The single cell suspension, in a hydrodynamic focused stream, is percolated by a laser of a single wavelength. The laser excites the electrons of the fluorescent dye to an advanced energy level. Afterwards, the electrons decline to their basal level under release of energy in terms of photons. The value of emitted photons recorded by a photon detector is proportional to the value of labeled molecules or antibodies per cell. The forward scatter (FSC) detector is in line

with the laser beam and its magnitude is roughly proportional to the cell size and volume. The side scatter (SSC) detector gives information about the granularity and complexity of the cell. The contemporaneous measurement of several fluorescence dyes is possible, if the used dyes became excited by the same laser (Argon laser, 488 nm) but emitted differentially at the specific emission spectra of the dye. If the emission spectra of the used dyes overlap, the signal of the detectors has to be compensated in order to avoid wrong positive or negative results.

Figure 9: Setup of flow cytometer

The sample becomes hydrodynamic focused in a liquid stream and disposed to laser of a single wavelength. The incidental fluorescent and scattered light is conducted by dichroic mirrors and optical filters to photomultipliers. The detectors convert this energy to electric signals that can be analyzed (adapted from:²¹⁵).

3.2.6.1 Analysis of apoptosis and necrosis

Specific changes in the plasma membrane can be described as early events of apoptosis. In this state of apoptosis, phosphatidylserine (PS) lost its asymmetric distribution across the phospholipid bilayer and is translocated from the inner leaflet of the plasma membrane to the extracellular leaflet at the cell surface^{216,217}. This process marks the cell for phagocytosis. Annexin V belongs to a family of calcium-dependent phospholipid-binding proteins which preferentially bind to PS and can be used as fluorescence marker, in a calcium dependent manner^{217,218}. The described translocation of PS occurs as well during necrosis, but in case of necrosis the cell membrane loses integrity. Therefore, apoptosis and necrosis can be differentiated by the use of propidium iodide (PI) staining the DNA in necrotic cells (see Figure 10).

Figure 10: Schematic illustration of apoptosis and necrosis detection using Annexin V

Reorganization of plasma membrane develops in the early process of apoptosis. Annexin V stained cells that are used to indicate cell membrane changes. The early initiation of apoptosis disrupted the characterized cell surface phospholipid asymmetry. Then the phosphatidylserine, presented in the inner cell membrane, migrates through the plasma membrane. Annexin V specifically bound to phosphatidylserine in the presence of protein-dependent Ca^{2+} representing the early apoptotic process (adapted from: ²¹⁹).

To analyze, if the treatment of ZnO NP initiates apoptosis or necrosis, 650,000 cells per flask were counted, seeded and incubated overnight for adherence. Afterwards, cells were treated with ZnO NP (15-18 nm) with a final concentration of 100 $\mu\text{g}/\text{mL}$ for 1 min, 15 min, 30 min, 1 h, 2 h, 3 h, 4 h, 5 h and 6 h. The staining of apoptosis was controlled by FITC Annexin V and necrosis by PI, respectively. After incubation, the medium was gathered in a tube and PBS after cells washing, respectively. Cells were detached using 1 mL StemPro® Accutase® Cell Dissociation Reagent for 5 min at 37°C. The cells were centrifuged for 5 min at 300xg, then the supernatant was discarded and the pellet was washed for two times with cell staining buffer. The cells were resuspended in 100 μL 1x Annexin V Binding Buffer containing 5 μL FITC Annexin V and 10 μL PI and were incubated at RT in the dark for 15 min. Prior to the measurement, 400 μL of the 1x Annexin V Binding Buffer were added to the cells. The cells were analyzed by the use of a flow cytometer with wavelength at 488 nm and emission wavelength for FITC at 518 nm and PI between 562 and 588 nm. FACS analysis was performed with a BD FACS Canto II apparatus and data were analyzed by using the FlowJo 7.6.3 software.

3.2.7 Fluorimetric assays

3.2.7.1 ROS Assay

The generation of reactive oxygen species (ROS) at different points in time was assessed in A549 cells using 2,7-dichlorofluorescein diacetate (H₂DFCDA). The non-fluorescent compound H₂DCFDA is de-esterified and oxidized in presence of ROS to fluorescent 2',7'-dichlorofluorescein (DCF). ROS generation was studied by fluorimetric analysis analogous the publication of *Wan et al. (1993)*²²⁰. Cells (200,000 per well) were seeded in 6-well plates and allowed them to adhere for 24 h. Five different treatments were investigated: single treatment with ZnO NP, ZnCl₂, ZnO NP + NAC, ZnO NP + DTPA, and ZnO NP + BSA (see 3.2.4.1, 3.2.4.2, 3.2.4.3, 3.2.4.4, and 3.2.4.5). As positive control of ROS, 500 nM and 1 mM of H₂O₂ were used and the cells were incubated with H₂O₂ in cell culture medium until the end of measurement. The cells were incubated with H₂DCFDA (100 μM) at 37°C for 30 min. The reaction mixture was removed and the cells were washed with 2 mL PBS. Afterwards, the cells were covered with 2 mL cell culture medium containing ZnO NP or ZnCl₂ (100 μg/mL). Fluorescence intensities were measured after 1 min, 15 min, 30 min, 1 h, 2 h, 3 h, 4 h, 5 h, and 6 h using a fluorescent microplate reader at an excitation wavelength of 485 nm and emission wavelength of 528 nm. The values were expressed as percentage of fluorescence intensities relative to the controls.

3.2.7.2 Measurement of mitochondrial membrane potential

The impairment of the mitochondria is a distinctive characteristic of early stages of apoptosis. This mitochondrial damage is further associated with changes in the mitochondrial membrane potential ($\Delta\Psi_m$). The mitochondrial permeability transition pore (MPTP) enable ions and small molecules the passage from the mitochondrion to the cytoplasm. The JC-1 dye is taken up from cells due to its lipophilic and cationic nature and selectively accumulates insight the electronegatively charged interior of mitochondria. JC-1 accumulates as J-aggregates in healthy mitochondria (Em: 590 nm) and after depolarisation the changes in $\Delta\Psi_m$ cause the release of monomers of JC-1 through the MPTP into the cytoplasm resulting in a shifting of emitted light to 530 nm. To analyze the changes of $\Delta\Psi_m$ after ZnO NP and ZnCl₂ treatment, 200,000 cells were seeded in a 6-well plate and treated with 2 μM JC-1 at 37°C for 30 min. The positive control was treated additionally with 100 mM CCCP, a protonophore, to depolarize the mitochondrial membrane. After incubation, the cells were washed three times with PBS. The cells were covered with 2 mL cell culture medium and the data were obtained using

3 Materials and methods

a fluorescent microplate reader (Ex: 485 nm, Em: 538 nm and 600 nm). The measurement was performed after 1 min, 15 min, 30 min, 1 h, 2 h, 3 h, 4 h, 5 h, and 6 h, and values were expressed as percentage of mitochondrial membrane potential ($\Delta\Psi_m$) calculated by following formula:

$$(\Delta\Psi_m) \% = \frac{\text{Fluorescence JC - 1 (600 nm)} / \text{Fluorescence JC - 1 (538 nm)}}{\text{Fluorescence CCCP (600 nm)} / \text{Fluorescence CCCP (538 nm)}} * 100$$

Formula 3: Calculation of mitochondrial membrane potential

($\Delta\Psi_m$) = mitochondrial membrane potential, JC-1 = 5,5',6,6'-Tetrachloro-1,1',3,3'-tetraethyl-imidacarbocyanine iodide, CCCP = Carbonyl cyanide *m*-chlorophenyl hydrazone

3.2.7.3 Fluorescence microscopy of $\Delta\Psi_m$

The changes of the mitochondrial membrane potential were performed using a fluorescence microscopy. The cells (approx. 200,000) were seeded on cover slips in a 6-well plate and treated with 2 μ M JC-1 at 37°C for 30 min. CCCP was used as positive control and the cells were treated additionally with 100 mM of the protonophore. After incubation, the cells were washed three times with PBS and incubated with 100 μ g/mL of ZnO NP or ZnCl₂ for 1 min, 15 min, 30 min, 1 h, 2 h, 3 h, 4 h, 5 h and 6 h. The cells were washed three times with PBS and fixed with 4 % paraformaldehyde for 15 min. After another washing step with PBS the cover slips were mounted on slides using fluorescence mounting medium. The slides were examined using an inverted fluorescence microscope.

3.2.7.4 AlamarBlue® Assay

The AlamarBlue® Assay serves for analysis of cellular viability. The assay is based on a redox indicator that provides a colorimetric change and fluorescent signal in response to metabolic activity of cells²²¹. In order to investigate the effects of ZnO NP on the cellular viability 15,000 cells/well were seeded in a 96-well plate and cultivated overnight. The cells were treated with ZnO NP (see 3.2.4.1) at three different concentrations (0.1, 10 or 100 μ g/mL), respectively. The negative control for viability was incubated with 100 μ L of 100 % ice cold EtOH for 10 min. Afterwards, the medium was replaced with 200 μ L fresh cell culture medium containing 10 % AlamarBlue® (10 % v/v). Subsequently, the cells were incubated at 37°C for 3 h. The data were obtained using a plate reader (Ex: 540 nm, Em: 600 nm).

3.2.7.5 Crystal violet Assay

After measurement of cellular viability using AlamarBlue[®] Assay the results have to be compared to the total cell amount per well. For this, the cells were washed three times with PBS and a 0.2 % crystal purple solution (50 µL/well) was added to each well and incubated at 37°C for 10 min. After incubation time the cells were washed again and treated with 40 µL of 10 % acetic acid for lysis. The cell amount was measured on a microplate reader at 540 nm. Results of AlamarBlue[®] Assay were related to results of Crystal violet Assay and then the treated cells were referred to the untreated controls. Untreated control is set as 100 % of viability.

3.2.7.6 γH2A.X immunofluorescence Assay

The γH2A.X immunofluorescence assay is based on the fast phosphorylation of the histone H2A.X as a sensitive marker for DNA DSB^{222,223}. The DNA damaging potential of ZnO NP, ZnO bulk and ZnCl₂ was analyzed using the γH2A.X immunofluorescence assay. Cells (approx. 200,000) were cultivated on cover slips in 6-well plates. Three different concentrations of ZnO NP (0.1, 10 or 100 µg/mL) were investigated as well as two pretreatments (see 3.2.4.2), and BSA stabilized ZnO NP (see 3.2.4.4), ZnCl₂, and ZnO bulk (see 3.2.4.5). After 1 min, 15 min, 30 min, 1 h, 4 h, and 24 h cells were fixed (15 min with 4 % paraformaldehyde and 10 min with methanol) and then washed with PBS. Nonspecific staining was blocked by incubation with 5 % BSA/PBS, 0.3 % Triton X-100 for 60 min. The cells were incubated with the primary antibody, anti-phospho-Histone H2A.X (Ser139, 1:500) diluted 1:500 in PBS with 0.3 % Triton X-100 at RT following by washing two times with PBS. The secondary antibody (Alexa Fluor 488 goat anti-mouse IgG) was applied at RT for 1 h. Then cells were washed two times in PBS, incubated in TBS with 400 mM NaCl for 2 min before getting washed again in PBS. The cover slips were mounted on slides using Vectashield[®] Hard+Set[™] Mounting Medium with DAPI. All slides were examined using an inverted microscope. For quantitative analysis foci were counted using the software Image J 1.47f²²⁴. At least, 60 cells were analyzed for each preparation. The foci amounts of each point in time were referred to the untreated control. The untreated control is set as 100 % of viability.

3.2.7.7 Immunostaining of primary cells of mucosa

Primary cells were seeded on a cover slip (approx. 200,000 cells) and incubated at 37°C and 5 % CO₂ overnight. The cells were washed three times with PBS and afterwards fixed with 4 % paraformaldehyde for 15 min. After this fixation step, cells were washed again three times with PBS and incubated for 5 min with TBS/Tween₂₀. To block nonspecific interactions, cells were incubated with 1 % BSA/PBS (1:10) for 60 min. The cells were incubated with a primary antibody for epithelial cells (anti-cytokeratin 13, 1:100) or fibroblasts (anti-FGFR4, 1:50) diluted in 1 % BSA/PBS at 4°C overnight. Cells were washed twice with TBS/Tween₂₀ for 5 min. The secondary antibody (Goat-anti-rabbit, biotinylated) was incubated in a dilution of 1:250 in 1 % BSA/PBS at RT for 30 min. Afterwards, cells were washed two times with TBS/Tween₂₀ and were incubated with Streptavidin/HRP conjugated in a dilution of 1:200 in 1 % BSA/PBS at RT for 30 min. The negative control was incubated with 2 mL of hämalaun solution for 5 min; afterwards the cells were washed with tap water for 5 min. In the next step, cells were washed again with TBS/Tween₂₀ for two times and covered on a slide with 3,3'-diaminobenzidine (DAB). The staining was analyzed using an inverted light microscope.

3.2.8 Biochemical methods

3.2.8.1 Total protein extraction

Cells were pretreated with NAC or DTPA (see 3.2.4.2, 3.2.4.3) and ZnO NP or were single treated with ZnO NP and ZnCl₂ (see 3.2.4.1, 3.2.4.5). The epidermal growth factor (EGF) served as positive control just for Erk and Akt activation. The cells were treated with 10 nM EGF for 15 min, prior lysis. The cells were scratched and the cellular proteins were extracted in 200 µL 4x lysis buffer after ZnO NP incubation after 1 min, 15 min, 30 min, 1 h, and 4 h. The cellular protein extracts were transferred to a 1.5 mL tube and sonicated for 30 sec. Then, the extracts were centrifuged at 12,000xg and 4°C for 20 min. The supernatants were transferred to a new 1.5 mL tube and used for protein determination.

3.2.8.2 Protein determination

The protein determination was carried out using the Bio-Rad *DCTM* (detergent compatible) protein assay kit, which is based on colorimetric reactions following the Lowry assay²²⁵. The protein determination kit was used according to the Bio-Rad manufacturer's instructions.

3.2.8.3 Sodium dodecyl sulfate polyacrylamide gel electrophoresis

Figure 11: Illustration of gel electrophoresis, western blot and protein detection

Western blotting is used to detect the amount or activation level of a specific protein. The proteins were separated by electrophoresis in a polyacrylamide gel, known as SDS-Page. Then the gel was placed on a membrane between four buffer soaked filter papers in a blotting tank. The proteins in the gel were transferred to the membrane from cathode to anode by electrical current. Afterwards, the membrane was incubated with a specific antibody against to protein of interest. The secondary antibody is conjugated to HRP enabling the protein detection after reaction of HRP with a luminescent compound (adapted from:^{226,227}).

3.2.8.3.1 Preparation of acrylamide gel

Protein samples were analyzed by protein separation using a sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-Page) with a vertical electrophoresis chamber. Depending on the molecular weight of the analyzed protein, different acrylamide concentrations were used for the running gel (see Table 5). The prepared running gel solution was filled to three fourth between two glass plates with fixed 1.0 mm spacers and polymerized after covering with 70 % isopropyl alcohol at RT for 30 min. After gel curing the isopropanol was poured off and washed with distilled water. The 4 % stacking gel was added above the running gel. A silicone rubber comb was placed between the plates to create slots. After further 30 min of incubation, the acrylamide gel was ready to use for SDS-Page.

3.2.8.3.2 Gel electrophoresis

After removing the silicone rubber comb and seal, the glass plates were fixed in a vertical electrophoresis chamber and filled up with 1x running buffer. In the first slot, 5 μ L of PageRuler™ Prestained Protein Ladder was loaded. The protein samples were added to 4x lysis buffer with 2.5 mM dithiothreitol (DTT) and denatured at 95°C for 10 min before the lysates were carefully loaded (final concentration: 30 μ g/30 μ L) into the slots of the stacking gel. The acrylamide gel ran at 15 mA/gel for the first 30 min and afterwards at 30 mA/gel with maximal voltage until the bromophenol blue band reached the bottom of the running gel.

3.2.8.3.3 Western blot analysis

The acrylamide gel was blotted to a nitrocellulose membrane using an electrophoresis blotter²²⁶. The gel was replaced between the nitrocellulose membrane and four slides of blotting paper on each side (see Figure 11) presoaked with transferring buffer in an electrophoresis blotter. The proteins were transferred to the nitrocellulose membrane at 1.5 mA/cm² of acrylamide gel at RT for 1.25 h. The membrane was washed once in washing buffer and was then blocked with blocking buffer (3 % or 5 % powdered milk concentration depending on protein, which has been analyzed), at RT for 1 h (see Table 6). After three washing steps for 5 min each, the membrane was incubated with the primary antibody diluted in blocking buffer under shaking conditions at 4°C overnight. The membrane was washed again 3x 5 min with washing buffer prior to incubation with a horseradish peroxidase (HRP)-linked secondary antibody at RT for 1 h. Then the membrane was washed again 3x 5 min with washing buffer. The used antibodies and dilutions are listed in Table 6. The respective antibodies were detected using enhanced chemiluminescent reagent (Western Lightning Plus - ECL) in a dilution 1:1 ratio by addition to the blotting membrane for 3 min. The immunostained proteins were recorded by the use of a ChemiDoc MP system. Band densities were normalized to the housekeeping protein β -actin or the total amount of protein and expressed as percentage of the respective controls.

3.2.8.3.4 Membrane stripping

For detection of additional proteins (e.g., housekeeping protein), the used membranes were stripped with stripping buffer for 30 min and further by 1 % SDS in distilled water for 30 min again, both at RT. The membranes were then washed 3x 5 min with washing buffer. The membrane was further treated with additional antibodies as mentioned before (see 3.2.8.3.3).

3.2.8.4 Human Phospho-ATM (S1981) ELISA

The biological impact of ZnO NP and ZnCl₂ on DNA damage signaling was further analyzed using the phosphorylation status of the respective phosphatidylinositol-3-kinases related kinases ATM, the main sensor of DNA DSB and activator of DNA damage response. The ELISA Kit Duo Set® IC Human Phospho-ATM was used to determine the phosphorylated amount of ATM in dependence of ZnO NP and ZnCl₂ treatment. The measurement of phosphorylated human ATM in cell lysates was performed according to the standard protocol of the manufacturer. The cells were lysed in ELISA lysis buffer# 13 after incubation with 100 µg/mL of ZnO NP and ZnCl₂ and the following time steps: 1 min, 15 min, 30 min, 1 h and 4 h. Samples were then frozen until use. After dilution of the Phospho-ATM (S1981) capture antibody in PBS (final concentration 10 µg/mL) a 96- ELISA microplate was immediately coated with 100 µL/well at RT for 24 h. Next day, the capture antibody was replaced by PBS and each well was washed two times with PBS. The ELISA microplate was further blocked with 300 µL blocking buffer at RT for 1 h. After washing three times for 5 min with PBS, 100 µL of cell lysates or standard in IC Diluent# 4 were added and incubated at RT for 2 h. After the third washing step, 100 µL of the Phospho-ATM (S1981) detection antibody (final concentration: 200 ng/mL) was incubated at RT for 2 h. After another washing step, 100 µL of the streptavidin-HRP-solution was added and incubated at RT in the dark for 20 min. The ELISA microplate was washed again and 100 µL of substrate solution was added and incubated at RT in the dark for staining development for 20 min. Finally, 50 µL of stop solution was added and the optical density was measured using a microplate reader set at 450 nm and a wavelength correction of 540 nm.

3.2.9 Statistics

The experiments were reproduced at least three times with the exception of primary cells of mucosa data. Mean values as well as standard errors or standard deviation for all experiments were calculated. The statistical analysis of the cell experiments was carried out using a one-way analysis of variance (ANOVA) with Bonferroni post-hoc test, two-way analysis of variance (ANOVA), or student's t-test (for paired samples). The p-values provided are only descriptive: p-values ≤ 0.05 (*) were termed significant, p-values ≤ 0.01 (**) were termed highly significant and p-values ≤ 0.001 (***) extremely significant. The analysis was performed using GraphPad Prism 5.

4 Results

The following chapter facilitates insights into the genotoxic mechanisms of ZnO NP in a model of respiratory epithelia as results of this work. The chapter is subdivided into six parts. The first section deals with the characterization and solubility of the synthesized ZnO NP. In the second part the internalization, intracellular accumulation, and distribution of ZnO NP is documented. The third section outlines the toxicity of ZnO NP. In the fourth and fifth part the genotoxicity of ZnO NP is shown, especially the induction of DNA damages and the activation of DNA damage response. Finally, data concerning the genotoxicity of ZnO NP in primary cells of the mucosa are described.

4.1 ZnO NP preparation and characterization

The ZnO NP were prepared by the *Institute of Inorganic and Analytical Chemistry of Johannes Gutenberg University Mainz*, fabricating two different sizes of ZnO NP (4-5 nm and 15-18 nm). Characterization of the synthesized ZnO NP was performed using transmission electron microscopy (TEM) for size and X-ray diffraction (XRD) for ZnO NP crystallisation. The surface charge of the particles was analyzed using ζ -potential measurement. The solubility of ZnO NP was measured using atomic absorption spectroscopy (AAS). Results are detailed in the following sections.

4.1.1 TEM, XRD and ζ -potential measurements

The TEM images showed the presence of non-aggregated spherical particles homogeneously dispersed in high purity H₂O. The size distribution obtained from TEM showed an average size value of ZnO NP centered at 4-5 nm (Figure 12A) and 15-18 nm (Figure 12C). The phase identity and crystallinity of the ZnO NP was certified using XRD (Figure 12B and D). All reflections can be indexed to the ZnO structure (wurtzite) with the lattice parameters $a = 3.24 \text{ \AA}$, $c = 5.20 \text{ \AA}$ and space group (SG) P6₃mc. The ζ -potential of ZnO NP (4-5 nm) was defined as -1 mV and of ZnO NP (15-18 nm) as + 40 mV.

Figure 12: ZnO NP characterization by TEM and XRD measurement

(A) TEM image of synthesized ZnO NP (4-5 nm) and the corresponding (B) XRD pattern. (C) Shows the TEM image of ZnO NP (15-18 nm) and the corresponding (C) XRD pattern.

4.1.2 Solubility of ZnO NP

The concentration of Zn^{2+} in the supernatants after dispersion in high purity H_2O or cell culture medium was measured by AAS at different points in time (Figure 13). In Figure 13A the cumulated levels of released Zn^{2+} dissociated from ZnO NP (4-5 nm) are shown in a time-dependent manner. It could be observed that ZnO NP (4-5 nm) dissociated faster in high purity H_2O than in cell culture medium (~ 100 mg/L in high purity H_2O and ~ 50 mg/L in cell culture medium after 4 h). Figure 13B shows enrichment of Zn^{2+} in high purity H_2O and cell culture medium released from ZnO NP (15-18 nm) in a time-dependent manner. The larger particles (15-18 nm) showed as well a time-dependent release of Zn^{2+} in both solutions but in a smaller dimension in contrast to ZnO NP (4-5 nm). The Zn^{2+} concentration after ZnO NP (15-18 nm) treatment increased continuously in both solutions (~ 25 mg/L in high purity H_2O and ~ 35 mg/L in cell culture medium after 4 h). Furthermore, the larger particles were more dissociated in cell culture medium than in high purity H_2O .

4 Results

Figure 13: Cumulated solubility of ZnO NP in high purity H₂O and cell culture medium

The solubilities of ZnO NP (4-5 nm) and ZnO NP (15-18 nm) in high purity H₂O and cell culture medium are shown. (A) Time-dependent increase of Zn²⁺ in high purity H₂O and cell culture medium after incubation with ZnO NP (4-5 nm). The smaller particles dissociated faster in high purity H₂O than cell culture medium. (B) Time-dependent enrichment of Zn²⁺ in high purity H₂O and cell culture medium after treatment with ZnO NP (15-18 nm). The larger particles showed a reduced dissociation in comparison to the smaller particles. They further dissociated faster in cell culture medium than in high purity H₂O. N=1.

4.2 Intracellular localization and distribution of ZnO NP

4.2.1 Intracellular localization of ZnO NP measured by TEM

Transmission electron microscopy (TEM) gives information about cellular morphology, particle incorporation and cellular distribution. To investigate the intracellular localization of ZnO NP, TEM was performed after particle treatment for several points in time. Incorporated and distributed ZnO NP (4-5 nm) and ZnO NP (15-18 nm) after 1 h of exposure are shown in Figure 14 and Figure 15. Figure 14 shows the morphology and cellular uptake of ZnO NP (4-5 nm). Agglomerated ZnO NP (4-5 nm) were detected in the cytoplasm. As shown in Figure 15F, E, and G, incorporated ZnO NP (15-18 nm) were rarely localized in the cytoplasm, nucleus, mitochondria and nuclear envelope.

Figure 14: TEM analysis of ZnO NP (4-5 nm) treated A549 cells

A549 cells were incubated with 100 μg/mL ZnO NP. (A) Control without ZnO NP treatment. (B) 1 min, (C) 15 min, (D) 30 min, (E) 1 h and (F) 4 h incubation with ZnO NP. (E) Arrows point to the ZnO NP localized in the cytoplasm. Scale bar A, B, C, D, F: 5 μm; E: 2 μm; n = nucleus, c = cytoplasm. Magnification A-F: 2784x.

Figure 15: TEM analysis of ZnO NP (15-18 nm) treated A549 cells

A549 cells were exposed to 100 μg/mL ZnO NP. (A) Control without ZnO NP treatment. (B) 1 min, (C) 15 min, (D) 30 min, (E) (F) (G) 1 h and (H) 4 h incubation with the particles. (F) Arrows mark the aggregated ZnO NP, which are intracellular localized in cytoplasm and nuclear region. (E) Arrow points to the particles in mitochondria. (G) Arrow points to the particles between the cytoplasm and the nucleus in the nuclear envelope. Scale bar A, B, C, D, E, F: 5 μm; E: 500 nm; G: 1 μm. n = nucleus, c = cytoplasm, m = mitochondria and ne = nuclear envelope. Magnification A-G: 2784x, H: 6000x.

4.2.2 Intracellular increase of Zn²⁺ after ZnO NP treatment

The extra- or intracellular dissociation of ZnO NP as mechanism of genotoxicity is hypothesized. The cells were loaded with FluoZinTM-3, a detector of intracellular free zinc, and afterwards treated with ZnO NP (4-5 nm) or ZnO NP (15-18 nm). The intracellular accumulation of Zn²⁺ was analyzed by spectrofluorometer. Cells were pretreated with the cell impermeable chelator DTPA to complex Zn²⁺ specifically. Furthermore, the ZnO NP were stabilized by BSA to prevent dissociation. ZnO NP (4-5 nm) treatment entailed to a slight intracellular increase of Zn²⁺ concentration from 1 nM in the first seconds to a maximum of 2.5 nM after 60 min (Figure 16A). The exposure to ZnO NP (15-18 nm) showed a fast intracellular increase of Zn²⁺ (Figure 17A). The intracellular Zn²⁺ concentration enhanced in the first seconds to 10 nM and increased continuously to a level of 35 nM after 60 min (Figure 17A). The extracellular chelation of Zn²⁺ by DTPA resulted in a residual intracellular increase of Zn²⁺ to a maximum of 0.5 nM after 10 min, as seen after treatment with both sizes of ZnO NP (4-5 nm and 15-18 nm) (Figure 16B and Figure 17B). BSA stabilization of ZnO NP (4-5 nm) resulted in a slight increase of intracellular Zn²⁺ with a maximal level of 2.5 nM after 60 min (Figure 16C). Figure 17C shows an intracellular increase of Zn²⁺ up to 3 nM in the first seconds keeping this level constant until the end of measurement (Figure 17C). In summary, the ZnO NP (4-5 nm) as well as ZnO NP (15-18 nm) dissociate quickly extracellular and were taken up by the cells as Zn²⁺.

Figure 16: Spectrofluorimetric analysis of intracellular Zn²⁺-levels after ZnO NP (4-5 nm) exposure

Spectrofluorometric measurements of intracellular Zn²⁺ after ZnO NP, ZnO NP + DTPA and ZnO NP + BSA treatment. (A) The intracellular Zn²⁺ level increased in the first seconds of exposure from 0.1 nM to ~ 1 nM and increased afterwards continuously to a level of 2.5 nM after 60 min. (B) Pretreatment with DTPA resulted in no intracellular increase of Zn²⁺. (C) BSA stabilized ZnO NP (4-5 nm) showed an intracellular increase of Zn²⁺ comparable to treatment with pure particles. N=3.

4 Results

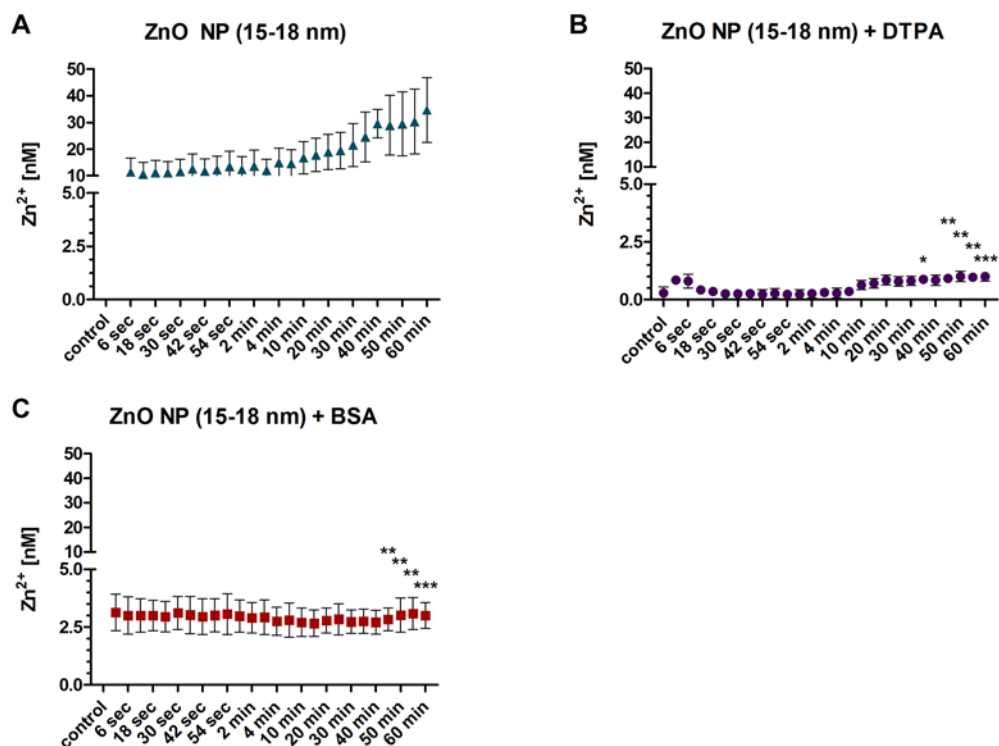

Figure 17: Spectrofluorimetric analysis of intracellular Zn²⁺ after ZnO NP (15-18 nm) exposure

Spectrofluorometric measurements of intracellular Zn²⁺ after ZnO NP, ZnO NP + DTPA and ZnO NP + BSA treatments. (A) ZnO NP (15-18 nm) exposure led to an increased intracellular Zn²⁺-level. The Zn²⁺-level raised to 10 nM in the first seconds and increased continuously to 35 nM after 60 min. (B) The pretreatment with DTPA resulted in no intracellular increase of Zn²⁺. (C) The BSA stabilized ZnO NP exposure led to an intracellular increase of Zn²⁺ up to 3 nM in the first seconds and retaining this level over the measurement. * = p<0.05, ** = p<0.01, *** = p<0.001 (ZnO NP (15-18 nm) + DTPA and ZnO NP (15-18 nm) + BSA in comparison to ZnO NP (15-18 nm)), at least N=3.

4.2.3 Intracellular distribution of Zn²⁺ after ZnO NP or ZnCl₂ treatment

To further evaluate the observed influx of Zn²⁺ (Figure 16 and Figure 17) cLSM live imaging of A549 cells was performed. FluoZinTM-3 was used as detector of free intracellular Zn²⁺ after ZnO NP or ZnCl₂ treatment. The cells were loaded with FluoZinTM-3 as mentioned in 3.2.5.2.1 and three compartments (early endosomes, endoplasmatic reticulum, and mitochondria) were co-localized by fluorescent dyes as described in 3.2.5.2.5, 3.2.5.2.6, and 3.2.5.2.7. The cells were treated with ZnO NP (4-5 nm), ZnO NP (15-18 nm) or ZnCl₂ and the localization of Zn²⁺ was detected each minute for finally 1 h.

4.2.3.1 Zn²⁺ distribution after ZnO NP (4-5 nm) treatment

The Zn²⁺-level did not increase in the early endosomes after particle treatment. Detected Zn²⁺ was of endogenous sources (Figure 18). In the endoplasmic reticulum (ER) no Zn²⁺ was detected after ZnO NP (4-5 nm) exposure (Figure 19). The treatment with ZnO NP resulted in a mitochondrial accumulation of Zn²⁺ after 10 min persisting until the end of measurement (Figure 20).

Figure 18: cLSM images of early endosomes after ZnO NP (4-5 nm) exposure

(A) Untreated A549 cells, loaded with FluoZinTM-3 and CellLight[®] Early Endosomes-RFP. Arrows point to Zn²⁺ accumulation in early endosomes under physiological conditions in untreated cells. (B) A549 cells loaded with FluoZinTM-3 and CellLight[®] Early Endosomes-RFP after 60 min of ZnO NP (4-5 nm) treatment. No accumulation of Zn²⁺ in early endosomes after ZnO NP (4-5 nm) exposure was detected. Arrows point to the Zn²⁺ accumulation in early endosomes before the particles were exposed. Green = FluoZinTM-3, red = CellLight[®] Early Endosomes-RFP, yellow = co-localization of Zn²⁺ with early endosomes. Scale bar: 10 μm.

Figure 19: cLSM images of ER after ZnO NP (4-5 nm) treatment

(A) Untreated A549 cells, loaded with FluoZinTM-3 and ER-TrackerTM Red. (B) A549 cells loaded with FluoZinTM-3 and ER-TrackerTM Red after 60 min of ZnO NP (4-5 nm) treatment. No distribution of Zn²⁺ in the ER was detectable after ZnO NP (4-5 nm) treatment. Green = FluoZinTM-3, red = ER-TrackerTM Red. Scale bar: 10 μm.

4 Results

Figure 20: cLSM images of mitochondria after ZnO NP (4-5 nm) treatment

Live imaging of A549 cells loaded with FluoZin™-3 and MitoTracker® Deep Red FM and treated with ZnO NP (4-5 nm). The images show an increase of Zn²⁺ in mitochondria after 10 min keeping this Zn²⁺-level in the period of time. The images on the right show an enlargement of the overlay images. Arrows point to the Zn²⁺ accumulation inside mitochondria. Co-localization of Zn²⁺ and mitochondria is indicated in the image as yellow overlay. Green = FluoZin™-3, red = MitoTracker® Deep Red FM. Scale bar: 50 µm.

4.2.3.2 Zn²⁺ distribution after ZnO NP (15-18 nm) treatment

The stained cells with FluoZinTM-3 and CellLight[®] Early Endosomes-RFP showed no co-localization of Zn²⁺ in early endosomes after ZnO NP (15-18 nm) treatment (Figure 21). No Zn²⁺ accumulation was detected in the endoplasmic reticulum after ZnO NP (15-18 nm) treatment (Figure 22). The exposure to ZnO NP (15-18 nm) resulted in a continuous mitochondrial Zn²⁺ accumulation until 20 min of exposure. Afterwards, the Zn²⁺-level is kept constant until the end of measurement (Figure 23).

Figure 21: cLSM images of early endosomes after ZnO NP (15-18 nm) exposure

(A) Untreated A549 cells loaded with FluoZinTM-3 and CellLight[®] Early Endosomes-RFP. (B) A549 cells loaded with FluoZinTM-3 and CellLight[®] Early Endosomes-RFP after 60 min of ZnO NP (15-18 nm) treatment. No accumulation of Zn²⁺ in early endosomes could be observed. Green = FluoZinTM-3, red = CellLight[®] Early Endosomes-RFP. Scale bar: 10 μm.

Figure 22: cLSM images of ER after ZnO NP (15-18 nm) treatment

(A) Untreated A549 cells, loaded with FluoZinTM-3 and ER-TrackerTM Red. (B) A549 cells loaded with FluoZinTM-3 and ER-TrackerTM Red after 60 min of ZnO NP (15-18 nm) treatment. No accumulation of Zn²⁺ in ER after ZnO NP (15-18 nm) treatment was detected in A549 cells. Green = FluoZinTM-3, red = ER-TrackerTM Red. Scale bar: 10 μm.

Figure 23: cLSM images of mitochondria after ZnO NP (15-18 nm) treatment

Live imaging of A549 cells loaded with FluoZin™-3 and MitoTracker® Deep Red FM and treated with ZnO NP (15-18 nm). The images show a continuous increase of Zn²⁺ in mitochondria until 20 min keeping this Zn²⁺-level to the end of measurement. The images on the right show an enlargement of the overlay images. Arrows point to the Zn²⁺ distribution inside the mitochondria. Co-localization of Zn²⁺ and mitochondria is indicated in the image as yellow overlay. Green = FluoZin™-3, red = MitoTracker® Deep Red FM. Scale bar: 50 μm.

4.2.3.3 Zn²⁺ accumulation in A549 cells after ZnCl₂ exposure

The involvement of an appropriate reference material, (e.g., ZnCl₂) is essential in order to assess specific nanoparticle risks. As positive control for dissociated ZnO NP to Zn²⁺, the treatment with ZnCl₂ was investigated. Treatment with ZnCl₂ resulted in strong FluoZinTM-3 increments. Zn²⁺ in early endosomes could be observed in single endosomes after 1 min of ZnCl₂ treatment following by reinforced accumulation over the period in time (Figure 24). ZnCl₂ exposure resulted in a fast Zn²⁺ distribution at the ER after 1 min and increased until 10 min, keeping this level over the period in time (Figure 25). The accumulation of Zn²⁺ after ZnCl₂ treatment resulted in a fast mitochondrial accumulation until 1 min, keeping this high level of Zn²⁺ until the end of measurement (Figure 26). Some cells showed small constructed bodies containing FluoZinTM-3 after 10 min. The bodies enlarged their size continuously (Figure 26, light blue arrow), suggesting the beginning of apoptosis or maybe autophagy.

4 Results

Figure 24: cLSM images of early endosomes after ZnCl₂ exposure

Live imaging of A549 cells loaded with FluoZin™-3 and CellLight® Early Endosomes-RFP and treated with ZnCl₂. Zn²⁺ in early endosomes could be observed in single endosomes after 1 min of ZnCl₂ treatment following by reinforced distribution over the period in time. The images on the right show an enlargement of the overlay images. Arrows show the Zn²⁺ accumulation inside the early endosomes. Co-localization of Zn²⁺ and early endosomes is indicated in the image as yellow overlap. Green = FluoZin™-3, red = CellLight® Early Endosomes-RFP. Scale bar: 25 µm.

Live imaging of A549 cells loaded with FluoZin™-3 and ER-Tracker™ Red and then treated with ZnCl₂. ZnCl₂ exposure resulted in a fast Zn²⁺ accumulation in the ER after 1 min and increased until 10 min, keeping this level until the end of measurement. The images on the right show an enlargement of the overlay images. Arrows show the Zn²⁺ accumulation inside the ER. Co-localization of Zn²⁺ and ER is indicated in the image as yellow overlap. Green = FluoZin™-3, red = ER-Tracker™ Red. Scale bar: 25 µm.

4 Results

Figure 26: cLSM images of mitochondria after ZnCl₂ exposure

Live imaging of A549 cells loaded with FluoZin™-3 and MitoTracker® Deep Red FM and then exposed to ZnCl₂. ZnCl₂ treatment led to a fast accumulation of Zn²⁺ in mitochondria of A549 cells. The distribution of Zn²⁺ after ZnCl₂ treatment resulted in a fast mitochondrial accumulation until 1 min, holding this high Zn²⁺-level until the end of measurement. The images on the right show an enlargement of the overlay images. White arrows show the Zn²⁺ accumulation inside the mitochondria. The blue arrow points to the supposed apoptotic bodies. Co-localization of Zn²⁺ and mitochondria is indicated in the image as yellow overlap. Green = FluoZin™-3, red = MitoTracker® Deep Red FM. Scale bar: 25 µm.

4.2.4 Strong accumulation of Zn²⁺ in the nucleus

The cLSM measurement of intracellular Zn²⁺ accumulation illustrated a fast increase inside the nucleus after treatment with ZnO NP (4-5 nm, 15-18 nm) and ZnCl₂ (Figure 27). The treatment with ZnO NP (4-5 nm) resulted in a strong nuclear Zn²⁺ distribution after 10 min (+ 1062 %) and + 1729 % after 20 min. This level remained largely unchanged until the end of measurement (Figure 27A). ZnO NP (15-18 nm) treatment showed as well a fast Zn²⁺ distribution in the nucleus. FluoZinTM-3 enriched continuously in the nucleus after 10 min of treatment with ZnO NP (15-18 nm) achieving a maximum of + 611 % after 40 min compared to the control (Figure 27B). Figure 27C shows the Zn²⁺ accumulation in the nucleus after treatment with ZnCl₂. This exposure results as well in a fast nuclear increase of Zn²⁺ after 1 min, but not with the same intensity as shown for ZnO NP. This Zn²⁺ level was increased up to + 261 % after 10 min and remained until the end of measurement (Figure 27C). The cells of cLSM measurement in Figure 18-27 were analyzed using software Image J 1.47f and the intensity of FluoZinTM-3 in the nucleus of each point in time was referred to the untreated control. The control was set as 100 %.

Figure 27: Measurement of nuclear Zn²⁺ accumulation

Live imaging of A549 cells loaded with FluoZinTM-3, indicating Zn²⁺, and exposed to ZnO NP (4-5 nm, 18-15 nm) and ZnCl₂. All treatments resulted in a fast accumulation of FluoZinTM-3 in the nucleus. (A) Exposure to ZnO NP (4-5 nm) resulted in a fast and strong distribution of Zn²⁺ up to 1062 % after 10 min and with a maximum of + 1729 % after 20 min. (B) ZnO NP (15-18 nm) exposure resulted in a continuous Zn²⁺ distribution in the nucleus after 10 min with a maximum of + 611 % after 40 min compared to the control. (C) Treatment to ZnCl₂ led to a fast accumulation of Zn²⁺ in the nucleus after 1 min. This Zn²⁺-level was more increased after 10 min up to 261 % and holding this level until the end of measurement. * = p<0.05, ** = p<0.01, *** = p<0.001; N=3.

4.3 Toxicity of ZnO NP

4.3.1 Cellular viability after ZnO NP treatment

The toxicity of different ZnO NP concentrations was analyzed by Alamar Blue[®] assay using a reagent containing resazurin. This non fluorescent dye is oxidized to the fluorescent product resorufin by viable cells. Color intensity was then referred to the number of viable cells measured by crystal violet staining of the cells and compared to the control set as 100 %. Figure 28 shows the cellular viability after treatment with both sizes of ZnO NP (A: 4-5 nm, B: 15-18 nm) of three different concentrations (0.1 $\mu\text{g/mL}$, 10 $\mu\text{g/mL}$, and 100 $\mu\text{g/mL}$) over the period in time. Figure 28A shows no reduction of cellular viability after treatment with 0.1 and 10 $\mu\text{g/mL}$ of ZnO NP (4-5 nm). The exposure to 100 $\mu\text{g/mL}$ resulted in a continuous decrease of viability to ~ 50 % after 4 h (Figure 28A). In contrast, the exposure to 0.1 $\mu\text{g/mL}$ ZnO NP (15-18 nm) resulted in an increase of cellular viability up to 137 % and this level remained until the end of measurement (4 h) (Figure 28B). The treatment with 10 $\mu\text{g/mL}$ resulted in a similar increase. Exposure to 100 $\mu\text{g/mL}$ ZnO NP (15-18 nm) resulted in a slight decrease ending in a maximal reduction of 17 % after 4 h (Figure 28B).

Figure 28: Cellular viability after ZnO NP treatment

The cellular viability of ZnO NP (4-5 nm and 15-18 nm) was measured using Alamar Blue[®]. Three different particle concentrations of 0.1, 10, and 100 $\mu\text{g/mL}$ in A549 cells were applied. (A) 0.1 and 10 $\mu\text{g/mL}$ of ZnO NP (4-5 nm) resulted in no reduction of cellular viability. Treatment with 100 $\mu\text{g/mL}$ led to a continuous decrease of cellular viability. (B) The treatment with 0.1 $\mu\text{g/mL}$ ZnO NP (15-18 nm) resulted in an initial increase until 15 min and keeping this level. Exposure to 10 $\mu\text{g/mL}$ of ZnO NP (15-18 nm) led to a continuous increase until the end of measurement. The treatment with 100 $\mu\text{g/mL}$ resulted in a slight reduction of cellular viability. Square = 0.1 $\mu\text{g/mL}$, dot = 10 $\mu\text{g/mL}$, and triangle = 100 $\mu\text{g/mL}$; * = $p < 0.05$; N=3.

4.3.2 Stabilization of ZnO NP with BSA

Bovine serum albumin (BSA) was used to stabilize ZnO NP, preventing the particle dissociation to Zn^{2+} . The treatment with ZnO NP resulted in a strong reduction of cellular viability after 24 h. This effect became abolished by BSA stabilization of ZnO NP (Figure 29). The treatment with 100 $\mu\text{g}/\text{mL}$ ZnO NP (4-5 nm) caused ~ 80 % decrease of viable cells. This toxic effect was reversed by BSA coating and resulted in increased cellular viability compared to untreated control (Figure 29A). This effect can be seen likewise after treatment with ZnO NP (15-18 nm) (Figure 29B).

Figure 29: Analysis of viability after treatment with BSA coated ZnO NP

Cellular viability of A549 cells treated with ZnO NP and BSA stabilized ZnO NP after 24 h (100 $\mu\text{g}/\text{mL}$). (A) A549 cells treated with ZnO NP (4-5 nm). (B) A549 cells treated with ZnO NP (15-18 nm). BSA coating prevented cellular toxicity, while ZnO NP treatment caused ~ 80 % decrease of viable cells. * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$; N=3.

4.3.3 Measurement of intracellular reactive oxygen species

The generation of reactive oxygen species (ROS) may lead to DNA damages and is a discussed mechanism of nanoparticle induced toxicity. Intracellular ROS was analyzed after ZnO NP (4-5 nm, 15-18 nm) and $ZnCl_2$ treatment. ROS was determined using the compound $H_2DCF\text{-DA}$ after exposure to ZnO NP, $ZnCl_2$, ZnO NP + BSA (particle stabilization), ZnO NP + DTPA (Zn^{2+} chelating) and ZnO NP + NAC (ROS scavenging). Hydrogen peroxide was used as positive control of ROS generation. Figure 30 shows the levels of ROS in untreated cells (light grey dots) and the H_2O_2 treated cells (grey quarters = 500 μM , black triangles = 1 mM) as positive controls. The untreated cells showed a maximal ROS-level with + 150 % after 6 h. Treatment with 500 μM H_2O_2 resulted in a continuous increase of ROS, reaching a stable level of about 450 %

4 Results

after 2 h. A similar curve was found after treatment with 1 mM H₂O₂ reaching 630 % after 2 h.

Figure 30: ROS-levels in untreated and H₂O₂ treated cells

Measurement of intracellular ROS-levels in A549 cells after treatment with 500 μM and 1 mM H₂O₂ as positive control for ROS. The control showed the level of ROS in untreated cells with a maximal increase of ROS up to ~ 150 % after 6 h. The treatment to the positive controls resulted in a continuous increase of intracellular ROS-levels reaching saturation after 1 h. The control showed a slight increase of ROS after 3 h. N=3.

In Figure 31A and B the ROS data of ZnO NP treated A549 cells are shown. Moreover, the controls including ZnCl₂, NAC, DTPA, and BSA coated ZnO NP are represented. The ROS-levels of each treatment were referred to the control of each point in time. All treatments except ZnO NP + NAC showed an approximately 25 % up-regulation of intracellular ROS until the first 30 min of exposure (Figure 31A and Figure 31B). The pretreatment with NAC was able to reduce the ROS-level strongly at all points in time to ~ 14 % compared to the untreated controls. Both sizes of BSA stabilized ZnO NP were able to reduce ROS generation after 30 min down to ~ 15 %. In spite of extracellular complexing of dissociated ZnO NP (4-5 nm) a 15 % up-regulation of ROS in the first 30 min followed by a down-regulation to basal levels was observed. The complexation of ZnO NP (15-18 nm) resulted in a generation of ROS up to 115 % in the first 30 min followed by a down-regulation to basal levels. Single treatment with ZnO NP (4-5 nm) resulted initially in increased ROS-levels (approx. + 25 %). In comparison to ZnO NP (4-5 nm), the exposure to ZnO NP (15-18 nm), reached an intracellular ROS-levels of 117 % after 1 min, 124 % after 15 min, and increased continuously to a maximum of 155 % after 6 h. ZnCl₂, as control for Zn²⁺, led to increased intracellular ROS-levels comparable to ZnO NP treatment of both sizes until the first 30 min. After 30 min of ZnCl₂

exposure the ROS-levels increased further and achieved its maximum close to 200 % after 6 h.

Figure 31: Measurement of intracellular ROS-levels

Measurement of intracellular ROS-levels in A549 cells after treatment with ZnO NP (4-5 nm, 15-18 nm), pretreatment with NAC, DTPA, stabilization of particles with BSA, and ZnCl₂ exposure. (A) Treatment with ZnO NP (4-5 nm, pink triangle) as well as all pretreatments led to slightly increased intracellular ROS-levels (~ 25 %) after the first 30 min. Then all treatments declined to basal levels. Exposure to ZnCl₂ resulted in continuously increased ROS-levels, reaching ~ 200 % (green circle). (B) Treatments with ZnO NP (15-18 nm) led to an up-regulation of ~ 25 % in the first 30 min returning to basal levels thereafter or reaching ~ 200 % in the case of ZnCl₂ (green circle). ZnO NP (15-18 nm) treatment resulted in further accumulation of ROS to levels reaching 150 % compared to the control (blue triangle). * = p<0.05, ** = p<0.01, *** = p<0.001 (all treatments are referred to ZnO NP single treatment), N=3.

4.3.4 Measurement of mitochondrial membrane potential

High levels of intracellular ROS are associated with the depolarization of mitochondrial membrane potential ($\Delta\Psi_m$) and released cytochrome c (cyt c) that further leads to apoptosis¹²⁹. In order to investigate the mitochondrial response to ZnO NP and ZnCl₂, A549 cells were loaded with JC-1, a permeable, cationic, and mitochondrial specific fluorescent dye. JC-1 dye is subjected to form aggregates of multiple fluorophores in the highly electronegative environment of the mitochondrial matrix. The $\Delta\Psi_m$ was measured after ZnO NP (4-5 nm, 15-18 nm) and ZnCl₂ treatment by fluorescence spectroscopy (Figure 32A). The acquired fluorescence images after treatment with ZnO NP (4-5 nm), ZnO NP (15-18 nm), and ZnCl₂ were visualized by fluorescence microscopy (Figure 32B). Figure 32A shows that ZnO NP (4-5 nm, pink triangle) as well as ZnCl₂ (green circle) treatment led to similar results and showed no depolarization of $\Delta\Psi_m$. In contrast

4 Results

to these findings, the exposure to ZnO NP (15-18 nm, blue triangle) showed a continuous depolarization of $\Delta\Psi_m$ with a maximum decrease to 25 % after 6 h. In Figure 32B the fluorescence images of A549 cells loaded with JC-1 dye before treatment and after 6 h of exposure to ZnO NP (4-5 nm, 15-18 nm) and ZnCl₂ comparable to the spectrofluorometric measurements are shown. In healthy cells, JC-1 forms J-aggregates with intense red fluorescence as seen in Figure 32B (control). However, in cells with depolarized $\Delta\Psi_m$ the dye converted to monomers which exhibit green fluorescence (positive control, CCCP). Figure 32B shows the overlay images of red and green emission and demonstrates the $\Delta\Psi_m$ in A549 cells after 6 h.

Figure 32: Analysis of $\Delta\Psi_m$ after treatment with ZnO NP (4-5 nm), ZnO NP (15-18 nm), and ZnCl₂

(A) Spectrofluorimetric measurement of $\Delta\Psi_m$ in A549 cells after treatment with ZnO NP (4-5 nm, 15-18 nm) and ZnCl₂. Mitochondrial membrane integrity was not reduced by ZnO NP (4-5 nm) and ZnCl₂ treatment. Treatment with ZnO NP (15-18 nm) showed a continuously decrease of $\Delta\Psi_m$ to ~30 % after 6 h. (B) Corresponding fluorescence microscopy images of $\Delta\Psi_m$ in untreated and treated cells after 6 h of ZnO NP (4-5 nm and 15-18 nm) and ZnCl₂ treatment. Red = polarized $\Delta\Psi_m$; green = depolarized $\Delta\Psi_m$. ** = $p < 0.01$, *** = $p < 0.001$ (all treatments are referred to ZnO NP (15-18 nm) treatment), N=3.

4.4 DNA damage analysis after ZnO NP exposure

γ H2A.X immunofluorescence assay was performed to visualize and quantify DNA damages as well as the activation of DNA damage repair signaling after treatment with ZnO NP or ZnCl₂.

4.4.1 Concentration-dependent analysis of ZnO NP genotoxicity

Genotoxicity of ZnO NP has been analyzed in three different cell lines (A549, HNSCCUM-02T and NIH/3T3). The main uptake pathway of nanoparticles is by inhalation through the respiratory epithelia, therefore HNSCCUM-02T was used as a model for the primary upper contact area and A549 cells were used as model for the lower respiratory tract. NIH/3T3 cells served as fibroblast control. The cells were treated with 0.1, 10 and 100 μ g/mL ZnO NP and the generation of DNA DSB was evaluated using γ H2A.X immunofluorescence assay (see 3.2.7.6). The DNA damages after ZnO NP (4-5 nm) and ZnO NP (15-18 nm) treatments were investigated in three cell lines and the results are shown in Figure 33 and Figure 34.

4.4.1.1 Treatment of cell lines with ZnO NP (4-5 nm)

The treatment of all three cell lines with ZnO NP (4-5 nm) resulted in slight increase of DNA damages after 1 min (Figure 33A, B and C). A549 treatment with ZnO NP (4-5 nm) resulted in a concentration-dependent increase of DNA DSB after 15 min (Figure 33D), while the comparable treatments to HNSCCUM-02T- and NIH/3T3 cells showed no DNA damages (Figure 33E und F). The observed DNA damages in A549 cells after 15 min were not seen after 1 h presumably because of DNA damage repair activation (Figure 33G). NIH/3T3 cells reacted with a strong concentration-dependent phosphorylation of H2A.X to ZnO NP (4-5 nm) treatment (Figure 33I). Figure 33K showed a strong increase of DNA DSB in HNSCCUM-02T cells after 4 h of exposure (10 μ g/mL \triangleq + 1982 %, 100 μ g/mL \triangleq + 1992 %). Similar to HNSCCUM-02T cells, NIH/3T3 cells showed a strong phosphorylation of H2A.X after 4 h exposed to the highest ZnO NP concentration. After 24 h in all cell lines a dose-dependent increase of DNA DSB was observed and non remaining cells after treatment with the highest concentration were detected.

4.4.1.2 Treatment of cell lines with ZnO NP (15-18 nm)

ZnO NP (15-18 nm) treatment of HNSCCUM-02T cells with the highest concentration resulted in a strong generation of DNA DSB (+ 2924 %) after 1 min (Figure 34). In contrast, A549 and NIH/3T3 cells showed no or weak increase of DNA DSB. ZnO NP (15-18 nm) exposure to A549 cells with the highest concentration resulted in strongly increased DNA damages (+ 455 %) after 15 min (Figure 34D). The utilized treatments of HNSCCUM-02T cells resulted in the generation of DNA DSB applied to 0.1 and 10 µg/mL. DNA DSB in NIH/3T3 were observed in a dose-dependent increase after 15 min of ZnO NP exposure (Figure 34E und F). Treatment of NIH/3T3 resulted in no further DNA damages after particle exposure for 1 h, 4 h, and 24 h (Figure 34I, L, O). The exposure to the highest applied concentration resulted in increased DNA DSB in HNSCCUM-02T cells after 1 h and 4 h (Figure 34H und K). Treatments of A549 and NIH/3T3 cells led to no DNA damages after 1 h and 4 h of ZnO NP exposure (Figure 34G, I, J, and L). 24 h of particle exposure resulted in a dose-dependent increase of DNA DSB in A549 and HNSCCUM-02T cells as well as a weak increase in NIH/3T3 cells (Figure 34M, N, and O). After 24 h, no remaining cells were observed after treatment with highest concentration.

4.4.1.3 Analysis of ZnCl₂ genotoxicity in A549 cells

The genotoxicity of ZnCl₂ at comparable concentrations as used for ZnO NP treatments was analyzed in A549 cells. The treatment with ZnCl₂ showed early and strong increased DNA DSB after 1 min compared to 15 min observed for ZnO NP (15-18 nm). As seen after exposure to nanoparticles, foci counts per cell decreased in the following period in time. According to the observations made with the nanoparticles, the highest concentration of applied ZnCl₂ resulted in no detectable cells after 24 h, most likely because of cell death.

Figure 35: Analysis of DNA DSB after ZnCl₂ treatment of A549 cells

A549 cells were exposed to ZnCl₂ for the indicated points in time and concentrations. DNA DSB were quantified by γH2A.X foci analysis. DNA damages were strongly increased after 1 min of ZnCl₂ exposure. Treatment to the highest concentration resulted in no remaining cells after 24 h. * = p<0.05; N=3.

4.4.2 Time-dependent genotoxicity of ZnO NP, ZnO bulk and ZnCl₂

In order to investigate the time-dependent DNA damages after ZnO NP, ZnO bulk, and ZnCl₂ treatment, A549 cells were treated with the highest concentration of 100 µg/mL. Concerning the fast damaging effect of ZnO NP and ZnCl₂ as shown in 4.4.1.2 and 4.4.1.3 the measurement was made at several points in time until 4 h. The generation of DNA DSB was evaluated using γH2A.X immunofluorescence assay (see 3.2.7.6). Three different pretreatments with ZnO NP + DTPA (see 3.2.4.2), ZnO NP + NAC (see 3.2.4.3), and ZnO NP + BSA (see 3.2.4.4) were investigated. NP are supposed to have higher reactivity and therefore enhanced toxicity, because of their increased surface area to volume ratio. In addition to ZnO NP we used ZnO bulk material with reduced surface area to volume ratio to compare their genotoxic effects. ZnCl₂ was used as positive control for Zn²⁺.

4.4.2.1 Treatment of A549 cells with ZnO NP (4-5 nm)

The treatment with ZnO NP (4-5 nm) resulted in fast generated DNA DSB (up to 336 %) after 15 min indicated by γH2A.X immunofluorescence staining (Figure 36A). This fast increase of DNA damages is followed by a quick dephosphorylation of H2A.X to basal levels. To differentiate between the generation of DNA DSB caused by ROS or dissociated ZnO NP, the cells were pretreated with NAC or DTPA. ROS scavenging by NAC prior to the treatment with ZnO NP showed reduced DNA DSB after 15 min, but still a slight increase of γH2A.X up to 150 % after 30 min (Figure 36B). The complexation of Zn²⁺ by DTPA resulted in a similar result as shown for ROS scavenging with ~ + 150 % after 30 min of treatment (Figure 36C).

Figure 36: Quantification of DNA DSB after ZnO NP (4-5 nm) treatment

(A) Single treatment with ZnO NP (4-5 nm) resulted in increased DNA DSB up to 336 % after 15 min. This fast H2A.X phosphorylation is followed by recovery to basal levels until 4 h. (B) The particle treatment after ROS scavenging with NAC showed a slight increase of γ H2A.X up to 150 % after 30 min followed by dephosphorylation to basal levels. (C) The complexation of Zn^{2+} by DTPA resulted in H2A.X phosphorylation up to 170 % after 30 min. (D) Representative images of foci suitable to graph A-C are shown. N=3.

4.4.2.2 Treatment of A549 cells with ZnO NP (15-18 nm)

Immunostaining of γ H2A.X foci indicated a fast increase of DNA DSB after 15 min of ZnO NP (15-18 nm) treatment to 455 % of control (Figure 37A). This fast increase was followed by a fast desphosphorylation to basal levels prior to a second increase of foci counts after 1 h, keeping this level until the end of measurement. In Figure 37B the ROS-dependent generation of DNA DSB after ZnO NP (15-18 nm) + NAC treatment is shown. NAC was able to reduce γ H2A.X strongly, but DNA DSB remained high after 15 min (+ 61 %). The extracellular chelation with DTPA prior to ZnO NP treatment impaired DNA DSB completely (Figure 37C). Figure 37D shows representative γ H2A.X foci images.

4 Results

Figure 37: Quantification of DNA DSB after ZnO NP (15-18 nm) treatment

(A) The treatment with ZnO NP (15-18 nm) resulted in increased DNA DSB up to 455 % after 15 min. This fast increase after ZnO NP (15-18 nm) treatment is followed by fast dephosphorylation prior to a second, weaker, increase of foci numbers after 1 h until 4 h. (B) ROS scavenging by NAC was able to reduce the generation of foci after ZnO NP (15-18 nm) treatment, but the level of DNA DSB remain increased after 15 min (+ 61 %). (C) The extracellular complexation of Zn^{2+} by DTPA resulted in a complete inhibition of DNA DSB generation. (D) Representative images of γ H2A.X foci suitable for graphic A-C. * = $p < 0.05$; N=3.

4.4.2.3 Treatment of A549 cells with BSA stabilized ZnO NP

Bovine serum albumin (BSA) is able to stabilize ZnO NP (e.g., to reduce particle dissociation). The stabilization of ZnO NP (4-5 nm) using BSA resulted in DNA DSB up to ~ + 180 % (Figure 38A). DNA damages kept unchanged until 1 h and then were dephosphorylated to basal levels after 4 h (Figure 38A). BSA coated ZnO NP (15-18 nm) induced a weak phosphorylation of H2A.X up to 134 % after 30 min (Figure 38B).

Figure 38: Quantification of DNA damages after exposure to BSA coated ZnO NP

(A) The exposure to BSA coated ZnO NP (4-5 nm) resulted in a fast phosphorylation of H2A.X up to 180 % after 1 min keeping this level for 1 h. (B) The treatment with BSA stabilized ZnO NP (15-18 nm) induced the phosphorylation of H2A.X up to 134 % after 30 min followed by dephosphorylation of H2A.X, indicating reduced DNA DSB. N=3.

4.4.2.4 Treatment of A549 cells with ZnCl₂ and ZnO bulk material

In Figure 39 the generation of DNA DSB after ZnCl₂ treatment is shown. ZnCl₂ induced a two phase generation of DNA DSB. The phosphorylation of H2A.X was observed quickly and strongly with an up-regulation to + 412 % after 1 min followed by recovery to basal levels. The second peak of foci formation was observed after 4 h with + 556 % (Figure 39). In order to investigate the genotoxic response of A549 cells to ZnO bulk material in contrast to nanoparticulated material, cells were treated with ZnO bulk in the highest concentration (100 µg/mL) and for the same points in time as mentioned for ZnO NP. Treatment to ZnO bulk showed a DNA damaging potential. Figure 40 shows a strong phosphorylation of H2A.X generated by ZnO bulk after 30 min of exposure. ZnO bulk phosphorylated H2A.X up to 334 % after 30 min followed by a continued dephosphorylation of γH2A.X until 4 h (Figure 40).

4 Results

Figure 39: Quantification of DNA DSB after exposure to $ZnCl_2$

(A) The exposure to $ZnCl_2$ led to a similar biphasic generation of DNA damages in A549 cells as shown for ZnO NP (15-18 nm). The phosphorylation of $\gamma H2A.X$ showed two maxima after 1 min (+ 412 %) and 4 h (+ 556 %). (B) Corresponding representative $\gamma H2A.X$ images of A549 cells after treatment with $ZnCl_2$. N=3.

Figure 40: Quantification of DNA DSB after treatment with ZnO bulk material

(A) The exposure to ZnO bulk material showed a strong phosphorylation of H2A.X after 30 min. The ZnO bulk material activated H2A.X up to 334 % followed by a continued dephosphorylation of $\gamma H2A.X$. (B) $\gamma H2A.X$ images of treated A549 cells with ZnO bulk material. N=3.

4.5 DNA damage response signaling

The cellular response to DNA damages is mainly mediated by the ATM or ATR kinases. ATM is mainly phosphorylated in the presence of DNA DSB, whereas ATR is activated in response to DNA SSB. These sensor proteins recognize the DNA damage and transfer the signal to effector proteins such as Chk1, Chk2, p53, and p21 promoting the DNA DDR. To investigate the impact of ZnO NP and ZnCl₂ on the activation of DDR, phosphorylated ATM was analyzed by ELISA (see 3.2.8.4). The proteins pChk2, p53, p21, ATR, and pChk1 were investigated by Western blotting (see 3.2.8.3.3). All presented data based on ZnO NP (15-18 nm) and ZnCl₂ treatments in a final concentration of 100 µg/mL. In the following section, ZnO NP (15-18 nm) are just named ZnO NP.

4.5.1 Analysis of ATR/Chk1 pathway

ATR is related to DNA single strand breaks (DNA SSB) as frequently observed after ROS induced DNA damages. Neither ATR nor Chk1 activation was observed after treatment with ZnO NP. In Figure 41A the level of ATR phosphorylation is shown. No activation of ATR after ZnO NP exposure was observed. Figure 41C shows a representative Western blot corresponding to Figure 41A. In fact, it was observed that the downstream kinase of ATR, pChk1 was dephosphorylated after ZnO NP treatment starting after 30 min and lasting until the end of measurement (see Figure 41 B/D).

Figure 41: Western blot analysis of ATR/Chk1 pathway after ZnO NP treatment

(A) No phosphorylation of ATR was observed after ZnO NP treatment. (B) Reduced activation of Chk1 was observed after 30 min of ZnO NP exposure. (C) Representative Western blot of phosphorylated ATR referred to total ATR. (D) Representative Western blot of pChk1 referred to β -actin. N=3.

4.5.2 Analysis of ATM/Chk2 signaling

ZnO NP and ZnCl₂ treatment resulted in H2A.X phosphorylation representing DNA DSB (see 4.4.2.2 and 4.4.2.4). DNA DSB resulted in activation of DDR, especially in activation of ATM/Chk2 pathway. The ATM phosphorylation status was investigated after ZnO NP and ZnCl₂ treatment. The results of pATM quantification in A549 cells is shown in Figure 42A and B. Accordingly, ATM as the major kinase, activated after induction of DNA DSB, was activated up to ~ 200 % after 30 min. This level was kept until the end of measurement (Figure 42A). ZnCl₂ treatment activated ATM similar to ZnO NP but faster, reaching the level of 200 % already after 15 min (Figure 42B).

Figure 42: ELISA measurements of pATM after ZnO NP and ZnCl₂ treatment

A549 cells were exposed to 100 µg/mL of ZnO NP or ZnCl₂, respectively. (A) ZnO NP activated the ATM damage response pathway up to ~ 200 % after 30 min of exposure keeping this level until the end of measurement. (B) ZnCl₂ stimulated the phosphorylation of ATM more fastly after 15 min of exposure. ATM phosphorylation returned to basal level after 1 h. N=3.

4.5.2.1 Analysis of ATM downstream signaling

ZnO NP and ZnCl₂ induced DNA DSB as well as ATM activation, thus downstream signaling of ATM was evaluated. The activation of the effector proteins Chk2, p53, p21 after ZnO NP and ZnCl₂ treatment was observed. Chk2, p53, and p21 got activated during exposure to ZnO NP and ZnCl₂, respectively. In Figure 43A the phosphorylation of Chk2 is shown after ZnO NP treatment. Chk2 was increasingly activated starting 15 min after exposure until the end of measurement. The maximum pChk2 level during measurement was achieved with up to 174 % after 4 h (Figure 43A). Compatible with these data p53 was activated by ZnO NP only moderately and lately increased after 4 h to ~ 150 % (Figure 43B). In Figure 43E the slight activation of p21 after ZnO NP treatment is shown (+ 30 %). ZnCl₂ activated p21 up to 161 % after 4 h of exposure (Figure 43F). The exposure to ZnCl₂ led to a two phase phosphorylation of Chk2. In Figure 43B a slight activation of Chk2 after 15 min (+ 13 %) and a stronger phosphorylation after 4 h (+ 50 %) is shown. An equal level of pChk2 in ZnO NP and ZnCl₂ treated A549 cells was observed after 4 h (Figure 43A and B). P53 activation was also found after ZnCl₂ treatment. The activation of p53 up to 116 % was found after 4 h of ZnCl₂ treatment (Figure 43D). Figure 43G and H show the representative Western blots after ZnO NP and ZnCl₂ treatment.

4 Results

Figure 43: Western blot analysis of ATM downstream signaling after ZnO NP and ZnCl₂ exposure

Graph A, C, and E represent the results of ZnO NP treatment whereas B, D, and F represent the findings of ZnCl₂ treatment. (A) Chk2 phosphorylation increased continuously after 15 min until the end of exposure (4 h). (B) Slight phosphorylation of Chk2 after 15 min and stronger phosphorylation after 4 h of ZnCl₂ exposure. (C) Strong stabilization of p53, 4 h after ZnO NP exposure. (D) Stabilization of p53, 4 h after exposure to ZnCl₂. (E) Slight activation of p21 after ZnO NP treatment. (F) Strong activation of p21 by ZnCl₂ after 4 h. (G) and (H) showed the representative Western blots to graphic A-F. N=3.

4.5.2.2 Analysis of ATM downstream signaling after ROS scavenging and Zn²⁺ complexation

ATM/Chk2 signaling is activated by ZnO NP. To further evaluate the underlying mechanisms of Chk2/p53/p21 activation after ZnO NP exposure, we pretreated the cells with NAC and DTPA. Western blot analyses of pChk2, p53, and p21 were investigated after ROS scavenging and extracellular complexation of Zn²⁺. In Figure 44A and B the activation of Chk2 is shown after ROS scavenging and ZnO NP treatment. In absence of ROS we observed persisting increased pChk2 up to ~ + 125 % and this level was kept until the end of measurement. Figure 44C shows a continuous up-regulation of p53 despite ROS scavenging. The p53-level was comparable to the single treatment of ZnO NP without any substitutes (cf. Figure 43C). Figure 44E shows the up-regulation of p21 after ZnO NP + NAC treatment. P21 reached a level of + 150 % after 4 h of treatment (Figure 44E).

4 Results

Figure 44: Western blot analysis of ATM/Chk2 pathway after ZnO NP + NAC treatment

(A) ROS scavenging by NAC led to fast but weak activation of Chk2. The level of approx. + 125 % of pChk2 after 1 min is remained unchanged over the period in time. (C) NAC and ZnO NP treatments led to continuous p53 activation with maximum of ~ + 200 % after 4 h. (E) P21 was up-regulated after treatment with ZnO NP + NAC reaching + 150 % after 4 h. (B), (D), and (F) show representative Western blots of graphic A, C, and E. N=3.

The extracellular chelator DTPA was used to complex dissociated ZnO NP. Neither Chk2 nor p53 were phosphorylated, i.e., not activated (Figure 45). The complexation of Zn²⁺ led to a dephosphorylation of pChk2 after 15 min of ZnO NP exposure (Figure 45A and B). In Figure 45C the stabilization of p53 after 30 min of DTPA + ZnO NP treatment is shown. DTPA treatment resulted in slightly reduced p21 levels with recovery after 1 h (Figure 45E). All these data taken together suggest that the ATM/Chk2 activation after

ZnO NP treatment relies on dissociated Zn^{2+} without ROS as an intermediate damaging the DNA.

Figure 45: Western blot analysis of ATM/Chk2 pathway after ZnO NP + DTPA treatment

(A) The Chk2 kinase is deactivated after extracellular chelation of free Zn^{2+} after ZnO NP treatment. (C) P53 is slightly stabilized after 30 min. (E) P21 levels remained unchanged or were reduced in tendency until 30 min. (B), (D), and (F) show representative Western blots of graphic A, C, E. * = $p < 0.05$, ** = $p < 0.01$; N=3.

4.5.3 Apoptosis/necrosis after ZnO NP exposure

DNA damages and DDR activation may result in apoptosis as part of a cellular suicide mechanism. This event is accompanied by typical cellular changes that can be measured by flow cytometry. Cells were exposed to ZnO NP in a final concentration of 100 µg/mL and then stained with annexin V (AV) and propidium iodide (PI) (see 3.2.6.1). The cellular state was determined as live cell (PI -, AV -), early apoptosis (PI -, AV +), apoptosis (AV +, PI +) and necrosis (AV -, PI +) staining. After ZnO NP treatment of A549 cells, early apoptosis was induced (detected as PI-negative/AV-positive cells). Figure 46 shows the predominant cellular state after ZnO NP treatment as early apoptosis followed by apoptosis. ZnO NP led to early apoptosis + 150 % after 6 h in comparison to the untreated control (Figure 46, green). The apoptosis induced by ZnO NP is shown in Figure 46 (blue) with an up-regulation of 150 %. The necrosis (red) and cellular viability (yellow) decreased during the analyzed time (Figure 46).

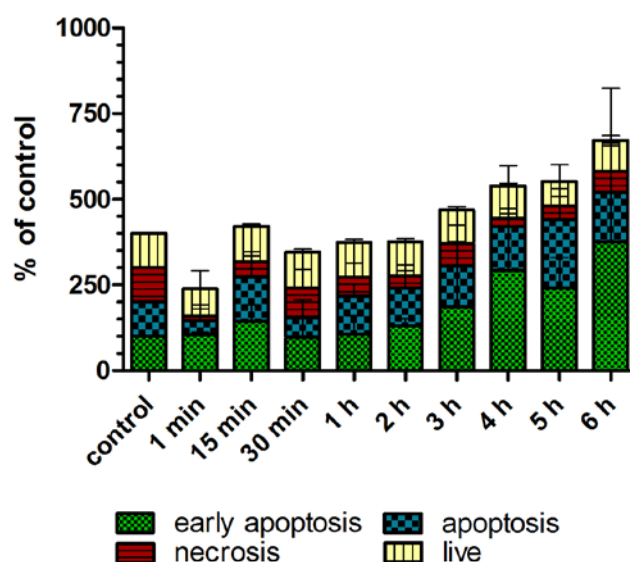

Figure 46: Flow cytometry analysis of apoptosis/necrosis after ZnO NP treatment

Cellular state of live, early apoptosis, apoptosis and necrosis were determined by AV/PI staining. ZnO NP exposure led to increased early apoptosis and slightly increases of apoptosis, while necrosis and viable cells are reduced in a time-dependent manner. N=3.

4.5.4 Activation of MAPK and PI3K pathways by ZnO NP

Nanoparticle toxicity is often associated with an activation of stress induced signaling. Here, two major pathways the MAPK/Erk and PI3K/Akt were investigated to get an overview of environmental stimuli triggered by ZnO NP or ZnCl₂. These activated signaling pathways lead to diverse cellular responses (e.g., proliferation, cell growth and apoptosis). In this study Erk1/2 and Akt were analyzed after ZnO NP and ZnCl₂ treatment. A549 cells were treated with 100 µg/mL ZnO NP or ZnCl₂ for 1 h and Western blot analyses were performed. EGF treatment was used as positive control for MAPK and PI3K pathway activation. The treatment with ZnO NP for 1 h caused an activation of both signaling pathways in terms of strong phosphorylation of Akt as well as Erk (Figure 47A, C and E). In Figure 47A the activation of Akt after ZnO NP treatment is demonstrated. It could be observed that the stimulation with EGF led to an activation of Akt up to 288 %. This activation of Akt was much higher after single treatment with ZnO NP resulting in an increase of phosphorylation up to + 1072 %. The combination of EGF stimulation and ZnO NP exposure did not cause an additive activation compared to the single exposure to ZnO NP (Figure 47A). In Figure 47B the activation of Akt is shown after ZnCl₂ treatment as positive control for dissociated ZnO NP. Akt was activated strongly and demonstrated a level of phosphorylation up to 3678 % compared to the untreated control. The combination with EGF led to an additional phosphorylation of + 722 %. The exposure to ZnO NP resulted in a phosphorylation of Erk up to 633 %. The combined treatment of ZnO NP with EGF caused a further phosphorylation to 786 % of Erk activation (Figure 47C). In Figure 47D the activation of Erk after ZnCl₂ treatment is demonstrated and shows a two times higher activation of Erk than observed after single treatment with ZnO NP. The high activation of Akt and Erk suggested that Zn²⁺ after dissociation of ZnO NP is the mediator in this cellular stress response. Figure 47E and F show exemplary Western blots adequate to Figure 47A, B, C and D.

4 Results

Figure 47: Activation of the MAPK/Erk- and PI3K/Akt-pathway after exposure to ZnO NP and ZnCl₂

The treatments with ZnO NP (15-18 nm) as well as with ZnCl₂ activate the MAPK/Erk- and PI3K/Akt-pathway. (A) and (C) The exposure to ZnO NP (15-18 nm) leads to a 6 times higher phosphorylation of Erk and a 10 times stronger phosphorylation of Akt compared to the controls. (B) and (D) This effect is multiply higher by the treatment with ZnCl₂. (E) and (F) Exemplary Western blots. (A, B) = pAkt, (C, D) = pErk. * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$; N=3.

4.6 Analysis of ZnO NP genotoxicity in primary cells of mucosa

In contrast to cell lines, primary cells are isolated from fresh tissue and used within the first passages. The cellular responses to ZnO NP exposure are assumed to be more similar to the *in vivo* situation than the results obtained from cell line experiments. To provide evidence of epithelial cells two different markers were used for primary cells of mucosa. Cytokeratin 13 was used as positive control for epithelial origin and FGFR4 as positive control for fibroblasts. Stainings confirm the epithelial origin of used primary cells (Figure 48).

Figure 48: Confirmation of epithelial origin of primary cells of mucosa

The immunohistochemical analysis of primary cells of mucosa showed a cytokeratin 13 positive result indicated as an intensive brown staining. FGFR4 staining was negative, represent as a slight or no brown staining (cf. negative control). This result confirms that the primary cells were of epithelial origin. Magnification: 400x.

The primary cells were obtained and used from four different patients. The γ H2A.X foci assays were realized comparable to the A549 cell line experiments in 3.2.4.1 and 3.2.7.6. Furthermore, the DNA damage response, downstream of ATM, was assessed after ZnO NP, ZnO NP + DTPA and ZnO NP + NAC treatment. The expression of the proteins Chk2, p53, and p21 was analyzed by Western blotting (see 3.2.8.3.3).

4.6.1 Analysis of DNA DSB after ZnO NP exposure

The influence of ZnO NP on primary cells of mucosal tissue (PMT) was evaluated by γ H2A.X immunofluorescence staining. Samples (PMT1-4) were treated as mentioned before (see 3.2.4.1 and 3.2.4). Treatment with ZnO NP resulted in PMT1 in fast and continuous increase of DNA DSB up to 944 % after 15 min of exposure (Figure 49A) followed by dephosphorylation of H2A.X to basal levels of untreated control. PMT1 reacted closely to the outcomes of A549 experiments (cf. Figure 37A). In Figure 49B the DNA damages in PMT2 after ZnO NP treatment is shown and demonstrated a fast increase of DNA DSB up to 580 % after 1 min of exposure. The strong phosphorylation was reduced to 153 % after 15 min and down to basal level after 30 min. Treatment of PMT2 showed a renewed phosphorylation after 1 h followed by dephosphorylation to basal level of untreated control (Figure 49B). Exposure of PMT3 with ZnO NP showed a slight but continuous increase of DNA DSB resulting in + 324 % after 4 h (Figure 49C). The result of PMT4 showed as well a fast increase of DNA DSB after ZnO NP treatment. H2A.X phosphorylation was up to + 602 % after 1 min keeping this level until 15 min of ZnO NP exposure. Afterwards the DNA damages were reduced to ~ 280 % until the end of measurement (Figure 49D).

Figure 49: Quantification of DNA DSB in primary mucosal cells after ZnO NP treatment

(A) PMT1 showed a fast and continuous up-regulation to 944 % of γ H2A.X after 15 min of exposure followed by dephosphorylation to basal level. (B) PMT2 demonstrated a fast increase of DNA DSB after 1 min of exposure ensued by reduction to 153 % after 15 min and a further activation of H2A.X after 1 h. (C) Treatment of PMT3 resulted in a slight but continuous increase of DNA damages of + 324 % after 4 h. (D) In PMT4, H2A.X is phosphorylated up to + 602 % after 1 min keeping this level until 15 min, then the DNA DSB are down-regulated to 278 %. N=4. PMT = primary cells of mucosal tissue, 1-4 represent patient, respectively.

4.6.2 Analysis of ATM downstream signaling in primary cells of mucosa

The analysis of ATM downstream signaling in A549 cells showed a strong activation of pChk2, p53, and p21 after 4 h of ZnO NP exposure (cf. Figure 43). The mucosal cells were treated with ZnO NP and ATM downstream signaling was analyzed using Western blotting. The signaling activation in primary cells of mucosa was analyzed in dependence of Zn²⁺ and ROS. After 4 h of ZnO NP exposure pChk2 was strongly activated and showed a phosphorylation-level up to 1200 % compared to the untreated control. This Chk2 activation was six times higher than the activation of pChk2 in A549 cells after 4 h. Zn²⁺ complexation resulted in a slight activation of pChk2 up to 200 % after 4 h. All treatments showed an increase of p53 of approx. ~ + 200 % compared to each control (Figure 50B). The treatment with ZnO NP resulted in an up-regulation of p21 after 4 h. In case of pretreatment with NAC or DTPA no activation of p21 was found (Figure 50C). Figure 50D shows the representative Western blots corresponding to Figure 50A, B and C. Cell lysates were corresponding to the patients of Figure 49 without PMT 3, because of weak cell amounts that were available for both experiments.

Figure 50: Analysis of ATM downstream signaling in primary cells of mucosa

(A) Chk2 was activated strongly after ZnO NP, slightly after ZnO NP + DTPA but not after ZnO NP + NAC treatment. (B) P53 after ZnO NP, ZnO NP + NAC, and ZnO NP + DTPA exposure resulted in an up-regulation to + 180 %. (C) The treatment with ZnO NP resulted in an up-regulation of p21 after 4 h. In case of pretreatment with NAC or DTPA no activation of p21 was observed. N=3.

5 Discussion

5.1 Toxicity of ZnO

The enormous increase of industrial applied ZnO NP, and the use of daily products containing ZnO NP, is attended with boosted environmental release and may result in health hazards. Therefore, the investigations on possible risk assessment of synthesized ZnO NP are inevitable. The primary contact organ for inhaled aerosols is the respiratory epithelia. For this reason the effect of ZnO NP on the respiratory epithelia, especially their possible toxicity, has to be analyzed.

5.1.1 ZnO NP impair the cellular viability of A549 cells

Both sizes of ZnO NP lead to a concentration-dependent toxicity (see Figure 28). The treatment of A549 cells with the highest concentration (100 µg/mL) results in a continuous decrease of cellular viability. The exposure to lower concentrations (0.1 µg/mL and 10 µg/mL) leads in case of ZnO NP (15-18 nm) to an increased viability respectively to no changes after treatment with ZnO NP (4-5 nm). The proved impairment of cellular viability of alveolar epithelial cells after ZnO NP exposure conforms to different studies in many types of cells²²⁸⁻²³³. The ZnO NP (15-18 nm) showed an improved toxicity in comparison to the ZnO NP (4-5 nm). These outcomes were surprising, because different working groups described that smaller particles are more reactive and further toxic, because of their larger surface to volume ratio, compared to larger particles²³. *Adamson et al. (2000)* determined ZnO NP as a component of atmospheric dust and to be a toxic factor, which is responsible for pulmonary reactivity after instillation to mouse lung²³⁴. Furthermore, the toxicity of ZnO NP was observed in bronchial cells of rats as well as human alveolar epithelial cells^{117,235,236}. This observed toxicity of ZnO NP could be caused by different damaging mechanisms. *George et al. (2009)* showed a reduced mitochondrial membrane potential as well as a loss of membrane integrity after treatment with ZnO NP in murine macrophages and BEAS-2B cells²³⁷. These outcomes confirm our results of reduced $\Delta\Psi_m$ after treatment with ZnO NP (15-18 nm). Some authors showed that ZnO NP damage cell membranes and lead to lowered mitochondrial activity in A549 cells^{238,239}. In addition, the increased production of inflammatory mediators such as IL-8, the generation of intracellular ROS, and the induction of apoptotic pathways are already described as toxic mechanisms of ZnO NP^{226,239,240,241}. *Hsiao et al. (2011)* also demonstrated decreased viability after treatment with smaller particles, while larger particles were less toxic²³⁹. Different parameters like size, surface charge and

agglomeration behavior of particles have an influence on dissociation and cellular uptake. The used particles have different ζ -potentials (see 4.1.1), which may explain the stronger toxicity of the larger particles. *Fröhlich (2012)* reviewed that positively charged particles cause more disruptions of plasma membrane integrity and mitochondrial damages than negatively charged particles²⁴². Alternatively, a connection between the ζ -potential and agglomeration behavior was observed by *Cho et al. (2012)*. They further described that the surface charge influences the inflammatory potential in rats²⁴³. Furthermore, *Bian et al. (2011)* observed that smaller particles often dissociate faster than larger particles²⁴⁴. In contrast, we found a faster dissociation and cellular uptake of the larger particles. Zn^{2+} dissociated from ZnO NP are often hypothesized as the main toxic mechanism^{245,246}. Therefore, we observed that the prevention of ZnO NP dissociation, using BSA coating, results in a complete inhibition of toxicity after exposure to ZnO NP (see Figure 29). This inhibition of toxicity by particle stabilization could also be observed in *in vivo* studies of rodent lung and zebrafish embryos exposed to iron doped ZnO NP¹⁸⁶. Dissociated particles in the supernatants of cell culture medium indicated a similar damaging potential as shown for ZnO NP in previous results of our working group^{247,248}. Analysis of alveolar epithelial cells cultivated in the air-liquid interface suppose the direct interaction of cellular structures with particles or by a local release of Zn^{2+} at the contact side of particles with the cells as underlying toxic mechanism^{223,236,237,249}. Furthermore, it is a matter of debate if Zn^{2+} , dissociated from particles, cause different cellular reactions than ZnO NP after local enrichment and both possibly act in synergistic way^{223,236,237,249}.

5.1.2 Toxicity through intracellular generation of ROS induced by ZnO NP

Another popular concept of nanoparticle toxicity is the intracellular release of ROS²⁵⁰. Under normal physiological conditions, the detoxification system and generation of ROS should be balanced in organisms. Based on the intracellular ROS-level, ROS serves as signaling molecule or could cause oxidative damages. The treatment of alveolar epithelial cells with ZnO NP (4-5 nm) results in slightly increased intracellular ROS-levels. Low ROS-levels are known to serve as signaling molecules and act as important physiological regulators of intracellular signaling pathways²⁵¹. The exposure to ZnO NP (15-18 nm) leads to reinforced generation of ROS (see Figure 31). Remarkably, the results in Figure 28 demonstrate increased counts of viable cells at low concentrations of ZnO NP (15-18 nm). This unexpected result might be explained by the observed slightly increase of ROS after ZnO NP (15-18 nm) treatment. The current study has also investigated MAPK/Erk- and PI3K/Akt signaling and we found activation, in the

case of ZnO NP as well as ZnCl₂ treatment. Zinc is a regulator of cell proliferation and *Huang et al. (2000)* postulated that Zn²⁺ and Ca²⁺ have synergistically effects on DNA synthesis and mitogenic signaling in fibroblasts²⁵². It is already described in literature, that generation of ROS is enhanced by intracellular Zn²⁺ and has the potential to stimulate growth promoting pathways^{253,254,255}. These suggestions correspond with the results in Figure 47 demonstrating the strong activation of Erk and Akt after nanoparticle treatment. Furthermore, the treatment with ZnCl₂ leads to stronger ROS-levels as well as an intensified Erk and Akt activation in contrast to ZnO NP (15-18 nm). *Seo et al. (2001)* demonstrated that the intracellular accumulation of Zn²⁺ resulted in the generation of ROS activating the MAPK/Erk pathway that further contributes to Zn²⁺ induced cell death²⁵⁵. These results are in line with the outcomes of the ZnO NP (15-18 nm) induced analysis of apoptosis (see Figure 46). Zn²⁺ is an essential cofactor for the activity of proteins involving in the reduction of oxidative stress (e.g., SOD and MT)²⁵⁶. The stress-related protein MT has antioxidant properties and protects cells against over production of ROS²⁵⁷. MT are cysteine-rich proteins with a low molecular weight. The protein has a high and specific affinity, mediated by their thiol groups of its cysteine residues, to bind biologic essential metals such as Zn^{256,257,258}. Increasing ROS-levels after ZnO NP treatment, as shown after 30 min of exposure, may lead to oxidation of the zinc binding thiol groups of MT, which further reduces the puffer capacity enhancing the damaging potential of additional Zn²⁺²⁵⁹. Additionally, in the present study, it could be observed that the complexation of Zn²⁺ by DTPA resulted in a complete inhibition of ROS. The release of Zn²⁺ is triggered by ROS and therefore oxidative distress seems to be a common constituent of different toxic signaling pathways in neurons²⁶⁰. This intracellular Zn²⁺ accumulation promotes the activation of harmful signaling processes such as the production of superoxide from 12-LOX that leads to further ROS production, initiating a positive feedback loop^{246,260,261}.

5.1.3 Toxicity through ZnO NP dissociation into Zn²⁺

In this study we observed a fast cellular intake of Zn²⁺ as well as a reduced viability. The pretreatment with DTPA resulted in initially reduced viability but recovered and is later completely abolished, proposing Zn²⁺ as main mediator of ZnO NP toxicity. The dissociation of Zn²⁺ from ZnO NP is discussed as possible mechanism of toxicity^{249,262}. Furthermore, we observed no reduction of viability after BSA stabilization, suggesting again Zn²⁺ as mediator of toxicity. *Xia et al. (2011)* also observed a reduced toxicity after doping ZnO NP with iron similar to the effects after the use of chelators¹⁸⁶. Previous results of our working group showed that Zn²⁺ ions released from ZnO NP in the

supernatant of the cell culture medium have similar toxic potential comparable to the exposition with ZnO NP^{233,247,262}. Air-liquid-interface models show no complete dissociation of ZnO NP and therefore the authors discussed their observed toxicity as effect of direct particle interactions with cellular structures and a high local release of Zn²⁺ at the particle-cell interaction side²³⁶. They suggested a different toxic mechanism based on ZnO NP and dissociated ions and discussed a possible synergistic cellular damage^{116,117,236,249}. We showed a fast decrease of cellular viability of ZnO NP exposed cells, while previous data of our working group represented a reduced cellular viability of ZnCl₂ treated cells just after 48 h compared to single particle treatment²⁴⁷. The treatment with ZnCl₂ resulted in an earlier generation of DNA DSB in comparison to the treatment with ZnO NP, suggesting possibly two different damaging mechanisms of mediated by released ions dissociated from particles in contrast to treatment with ZnCl₂. The zinc homeostasis is highly controlled by different zinc transporters and divalent cation transporters (DMT1) which regulate the zinc influx and efflux, leading possibly to retarded nanotoxicity. These results are confirmed by *Zhang et al. (2012)* in comparative experiments investigating the effects of intra- and extracellular Zn²⁺ on toxicity by exposing cells with ZnO NP and ZnCl₂²³³. Another possibility how Zn²⁺ may lead to cellular damages is by blocking the four complexes of mitochondrial respiration with different affinity as observed by other authors^{70,79,80,129}. *Fukui et al. (2012)* described a significant correlation between high intracellular Zn²⁺ levels and the generation of ROS²⁴⁰. We observed a fast intake of Zn²⁺, increased ROS-levels, continuously decreased $\Delta\Psi_m$, and induction of early apoptosis. ROS may react in a damaging way to mitochondria and DNA leading to apoptosis. Furthermore, an increased intracellular Zn²⁺ level leads to a destabilization of mitochondria mediated by the release of Ca²⁺²⁶³. This could be confirmed by *Kao et al. (2012)* who observed a strong increase of cytosolic and mitochondrial Zn²⁺ levels after ZnO NP treatment. These high levels of mitochondrial Zn²⁺ resulted in the depolarization of $\Delta\Psi_m$ and increased permeability which further leads to the activation of the intrinsic apoptosis pathway, confirming our outcomes⁷². These findings are a further proof of ZnO NP toxicity mediated by dissociated ions.

5.2 Solubility of ZnO NP

We hypothesized that the ZnO NP are quickly dissociated outside the cell and are internalised as Zn^{2+} or, in case of endocytic uptake, dissociate in the acidic endosomal environment²¹. We analyzed the ZnO NP solubility in high purity H_2O (pH 5.8) and cell culture medium (pH 7.4). Both sizes of ZnO NP showed a strong time-dependent dissociation in high purity H_2O and cell culture medium. ZnO is often classified in material safety data sheets as insoluble in H_2O , while others reported a highly pH-dependent solubility of ZnO^{188,189}. The existent pH in the solutions and the availability of ions might influence the surface charge of the particles and further the grade of agglomeration¹⁸⁸. Illés *et al.* (2006) postulated increased aggregation behavior of particles at any pH if electrolyte concentration is raising²⁶⁴. This possibly explains the reduced dissociation in cell culture medium in contrast to high purity H_2O because of the electrolytical components needed for cell survival in the medium. We further suggest that our observed time-dependent ZnO solubility is linked to the *Ostwald ripening phenomena*. This phenomenon describes that unstable surface ions usually dissolve diminishing the particles over the period in time, while the number of free ions in solution is increasing. If the solution is saturated with the free ions, those will redeposit on the surface of larger particles. This means, that smaller particles may dissociate, while larger particles grow and dissociate slowly in contrast to the smaller particles²⁶⁵⁻²⁶⁷. Borm *et al.* (2006) postulated that the rate of dissolution is proportional to particle surface area meaning that smaller particles, with an increased surface area, dissolve faster than larger particles for the same mass²⁶⁶. This possibly explains the faster dissolution of ZnO NP (4-5 nm) in comparison to ZnO NP (15-18 nm) observed in this study.

5.3 ZnO NP uptake

5.3.1 Size and charge dependent uptake of ZnO NP

The TEM-data of this study showed only very minor amounts of ZnO NP inside the cell. ZnO NP of both sizes were only detectable after 1 h of treatment. ZnO NP (4-5 nm) are rarely located in the cytoplasm, while ZnO NP (15-18 nm) are additionally infrequently localized in the mitochondria, nuclear envelope, and nucleus (see Figure 14 and Figure 15). Usually, the cellular uptake of nanoparticles takes place by endocytosis and is dependent on different factors such as size, form, and ζ -potential of the particles. The physico-chemical properties of the particle surface influence the interaction with cellular membranes. The negatively charged smaller particles are less detectable intracellularly in contrast to the positively charged larger particles using TEM measurement. Different

studies have shown that positively and negatively charged particles are taken up easier than neutral particles²⁴². The unspecific interactions of negatively charged particles with membrane receptors have been demonstrated, leading to enhanced cellular particle uptake²⁴². Nevertheless, it is no explanation of the less intracellular accumulation of both particle sizes in general. The infrequent detection of particles inside the cells using TEM and the observed fast dissociation in cell culture medium and high purity H₂O suppose a fast dissociation of ZnO NP. Therefore, two probably consecutive mechanisms of ZnO NP intake are suggested: first, the fast internalization of extracellular dissociated ZnO NP and second the endocytic uptake of solid particles and their subsequent intracellular dissociation into Zn²⁺ at low pH.

5.3.2 Intracellular accumulation of Zn²⁺

We measured the dissociation of ZnO NP by spectrofluorimetry and cLSM using FluoZinTM-3. Cellular treatment with ZnO NP (4-5 nm) resulted in a slight but continuously increased intracellular Zn²⁺ concentration, while the exposure to ZnO NP (15-18 nm) showed a fast and strong intracellular ion accumulation. To prove the concept of extracellular dissociation of ZnO NP, the cells were pretreated with the extracellular Zn²⁺ chelator DTPA prior to particle treatment. In both cases, pretreatment with DTPA resulted in no intracellular Zn²⁺ increase, confirming the assumed hypothesis of fast extracellular particle dissociation and uptake of Zn²⁺. An endosomal ZnO NP uptake was not detectable by TEM measurements. The dissociation of affiliated particles in the acidic environment of early endosomes was proven by cLSM measurements using FluoZinTM-3 detecting free Zn²⁺ in labeled endosomes (see 4.2.3.1, 4.2.3.2, 4.2.3.3). The treatments with ZnO NP of both sizes resulted in no endosomal uptake of ZnO NP and accumulation of Zn²⁺ in early endosomes. One might prompt that we found an endosomal independent mechanism of intracellular Zn²⁺ accumulation of dissociated ZnO NP. These findings disprove the popular hypothesis suggesting an endocytic ZnO NP uptake and dissociation in early endosomes at pH 5-6 as reported by *Kao et al. (2012)*⁷². *Xia et al. (2008)* showed an endosomal accumulation of FITC labeled and stabilized ZnO NP²⁶³. *Hackenberg et al. (2011)* also demonstrated the cellular uptake of ZnO NP coated with BSA⁷¹. However, these authors used stabilized ZnO NP; these particles are expected to dissociate slowly, enabling endocytic uptake of NP, which is different compared to our experiments, using unmodified ZnO NP. Accordingly to our data, *Valdiglesias et al. (2013)* observed in neuronal cells that none-stabilized ZnO NP are not incorporated²⁶⁸. Furthermore, it is important to emphasize that granular structures were observed before exposure to the cells. However, these structures were monitored

5 Discussion

at basal levels and became intensified in any case of exposure, i.e., with ZnO NP as well as ZnCl₂. Some studies reported that extracellular Zn²⁺ ions were absorbed by the cells and captured in specialized vesicles named zincosomes^{238,252,269,253}. The nature of these vesicles is still unknown but they have been detected in several cell types^{269,270}. These granular structures were discussed to have an endosomal origin²⁷¹. *Gojova et al. (2007)* found ZnO NP within vesicles in the cytoplasm. We observed as well vesicular structures, which possibly are zincosomes, in the cytoplasm but they contained Zn²⁺ that is dissociated extracellularly from ZnO NP²⁷². Further, *Gojova et al. (2007)* observed less vesicular embedding for ZnO NP in contrast to other metal oxide nanoparticles as well as impairments of the membrane through intercalated particles²⁷². In summary, the co-localization of Zn²⁺ in early endosomes after ZnO NP treatment was not detected. This data again support the hypothesis of cellular Zn²⁺ intake without the use of the endocytosis machinery. The cellular uptake of Zn²⁺, and the transport into and out of organelles, requires specific transport proteins spanning these membranes²⁷⁰. Two main families of eukaryotic zinc transporters, named ZIP and ZnT proteins, are known^{273,274}. The ZIP proteins transport Zn²⁺ from the extracellular space or organelle lumen, into the cytoplasm^{270,275}. The corresponding antagonists of the ZIPs are the ZnTs which are responsible for the Zn²⁺ transportation from the cytoplasm to organelles or outside the cell^{270,275}. *Gunshin et al. (1997)* described a cationic transporter known as divalent cation transporter 1 (DCT1) which binds a variety of divalent metals such as Zn²⁺²⁷⁶. The intracellular Zn²⁺ level is distributed to cytoplasm (50 %), nucleus (20-30 %), and are membrane associated (10-20 %). However, 90 % of total intracellular Zn²⁺ amount is bound to proteins¹⁹⁴. Our data showed a continuous increase of intracellular free Zn²⁺ concentration with + 35 nM after 1 h of treatment with ZnO NP (15-18 nm). Several studies analyzing different cell types report a total intracellular Zn²⁺ concentration in a range of <0.1 nM to 0.5 mM depending on the used methods^{270,277-279}. Low levels of Zn²⁺ are required for cellular Zn²⁺ homeostasis but in case of ZnO NP exposure a plus of 35 nM after 4 h possibly is enough for cellular imbalance. In this case the normal Zn²⁺ level is raised and efflux mechanisms mediated by ZnTs are necessary to prevent the cell of over accumulation and subsequently toxic consequences^{224,280,281}. The amount of released Zn²⁺ from ZnO NP is dependent on several factors e.g., pH, agglomeration behavior, cell culture medium as well as the experimental set-up^{245,282}. This fast Zn²⁺ dissociation and intake could play an essential role in ZnO NP toxicity.

5.3.3 Co-localization of Zn²⁺ with cellular organelles

The biological roles of zinc are mainly of structural, catalytical and regulatory functions. Zinc is essential as a structural element in protein folding as well as in macromolecular and enzyme stabilization (e.g., superoxide dismutase)^{269,283}. *Vallee and Falchuk (1993)* showed that zinc is a component of the catalytic site of many metalloenzymes¹⁹⁴. Furthermore, zinc is a regulator of different biological processes (e.g., gene regulation)^{269,280,284}. We observed that the Zn²⁺ after cellular intake shifted subsequently into mitochondria and nucleus but not in the ER.

5.3.3.1 Mitochondrial accumulation of Zn²⁺

Using TEM we rarely illustrated ZnO NP in mitochondria. Furthermore, we observed free Zn²⁺ in mitochondria after treatment with ZnO NP. The mechanism of mitochondrial Zn²⁺ uptake and function is not fully understood yet. Different metalloenzymes, such as Zim17, are localized in the matrix of mitochondria requiring Zn²⁺ as co-factor for their functions^{285,194}. *Maret et al. (2000)* and *Ye et al. (2001)* observed metallothionein (MT) in the intermembrane space of mitochondria and pointed out that MT may serve as source of increased Zn²⁺ concentrations within the matrix²⁸⁶. MT are able to detoxify ROS to maintain homeostasis. ROS is known to oxidize thiol groups of MT during respiration leading to release of Zn²⁺¹⁹⁸. We observed increased ROS-levels after 30 min of ZnO NP as well as ZnCl₂ treatment and in both treatments an increase of intracellular Zn²⁺-levels, assuming a release of Zn²⁺ from MT through oxidization by ROS. The released Zn²⁺ accumulates in the nucleus and activates the metal regulatory transcription factor 1 (MTF-1), the known activator of MT genes. MTF-1 binds with its four zinc finger domains to the promoters containing a metal-response element (MRE) of the MT gene, leading to MT transcription¹⁹⁸. We suppose that a physiological level of Zn²⁺ is important for mitochondrial homeostasis, because Zn²⁺ is necessary for ROS detoxification after binding to MT. We observed a depolarization of $\Delta\Psi_m$ after treatment with ZnO NP (15-18 nm), as well as the starting of early apoptosis events (discussed later). The $\Delta\Psi_m$ depolarize after Zn²⁺ overload, resulting in Zn²⁺ and cytochrome c (cyt c) release into the cytoplasm. Cyt c forms an apoptosom initiating the activation of several caspases leading to apoptosis²⁵⁴. *Sensi et al. (2003)* reported that the depolarization of $\Delta\Psi_m$ leads to an accumulation of Zn²⁺ in the cytosol released from mitochondria²⁵⁴. This effect was observed in neurons and is associated with cell death in diseases such as ischemia and epilepsy²⁸⁸. Many years ago it was postulated that Zn²⁺ is able to inhibit oxidative phosphorylation as well as all complexes of the respiratory chain, with dramatically outcomes for cell fate^{289,290}. *Medvedeva et al. (2014)* suggest, that the Zn²⁺ entry into

mitochondria led to ROS generation and resulted in mitochondrial dysfunction and played a role in the deregulation of Ca^{2+} ²⁹¹. They further blocked the Ca^{2+} uniporter by ruthenium red and showed a reduced mitochondrial Zn^{2+} uptake but no totally inhibition²⁹¹. We suppose that Zn^{2+} partially enters mitochondria by a pathway that naturally transports Ca^{2+} and the accumulation over the physiological level leads to toxicological effects in form of increased ROS-levels, reduced $\Delta\Psi_m$ and the initiation of the intrinsic apoptosis pathway.

5.3.3.2 Endoplasmatic accumulation of Zn^{2+}

Early data of our working group reported an ER swelling in form of homogenous perinuclear clouds after ZnO NP treatment²⁴⁷, that was also observed by *Chen et al. (2014)*²⁹². Due to this reported ER swelling we observed no Zn^{2+} inside the ER. *Chen et al. (2014)* postulated the presence of ER stress after ZnO NP treatment as cellular imbalance and initiator of apoptosis by activation of caspase-12, which is localized inside the ER²⁹². They analyzed the ER stress level using quantitative real-time PCR and found significant increased levels of *xbp-1s* mRNA (activator of UPR pathway)²⁹². *Chen et al. (2014)* proposed that ER stress is mainly associated with generated ROS mediated by ZnO NP or released Zn^{2+} . Subsequently the increased ROS-level could activate apoptosis and necrosis mediated by early signals of ER stress response²⁹². The lumen of the ER is the site for synthesis, folding, and assembling of proteins and many of these processes are Zn^{2+} -dependent^{256,270,292,270,293}. We observed no Zn^{2+} accumulation in the ER after treatment with ZnO NP but with this observation we can not confirm if ER stress is still present. We suggest that the observed ER swelling in earlier results of our working group is an indicator for ER stress but not directly mediated by ZnO NP and Zn^{2+} but rather indirectly by ROS.

5.3.3.3 Nuclear accumulation of Zn^{2+}

Interestingly, the TEM-data of A549 cells showed nanoparticles in the nuclear envelope as well as inside the nucleus (see Figure 15). Published data of our working group indicated a strong increase of nuclear Zn^{2+} after treatment with ZnO NP measured by AAS²⁴⁸. This data could be confirmed by cLSM measurement of A549 cells in the current study (see Figure 27). Treatment with both particle sizes resulted in a fast and strong accumulation of Zn^{2+} in the nucleus. Zn^{2+} is a possible second messenger and an integral part of the active center of multiple enzymes (e.g., carboanhydrase) and nuclear proteins (e.g., zinc finger transcription factors and zinc finger nucleases). Our group

measured higher levels of Zn^{2+} in the nuclear than the cytoplasmic fraction, considering the smaller volume of the nucleus showing a strong accumulation of Zn^{2+} in the nucleus²⁴⁸. These data suggested an active transport into this cellular compartment. The data fit to our hypothesis of a direct Zn^{2+} activity in the nucleus very well. *Weser et al. (1973)* showed a strong increase of nuclear Zn^{2+} in liver cells of rat and chicken, after *in vitro* and *in vivo* administration of $ZnCl_2$ ²⁹⁴. The nuclear uptake of Zn^{2+} is discussed as ATP dependent translocation of MT, in absence Zn^{2+} transporters in the nucleus^{295,296}. Zn^{2+} contributes in many important processes like gene expression at the site of nucleus. The generation of ROS resulted in oxidation of thiol groups, leading to release of Zn^{2+} storing proteins, such as MT and other proteins complexing Zn^{2+} by cysteine thiols. *Spahl (2007)* observed that exogenously applied nitrosative stress increases MT mRNA expression in a Zn^{2+} dependent manner released from MT²⁹⁷. The high level of Zn^{2+} inside the nucleus may interact directly to DNA through unknown mechanisms. Zn^{2+} might interact with negatively charged residues of DNA (e.g., the phosphates of the DNA backbone)^{298,299}. As mentioned before, high amounts of Zn^{2+} inside the nucleus may lead to toxicity especially genotoxicity in form of direct interactions with DNA to induce DNA damages.

5.4 Genotoxicity of ZnO NP

The permanent exposure of cells to ZnO NP may lead to DNA damages and might bear a possible mutagenic potential. For this reason, a possible DNA damaging potential, as well as DDR regulatory abilities were analyzed. In the following section the *in vitro* genotoxicity of ZnO NP (15-18 nm), and ZnCl₂ in A549 cells and primary mucosal cells will be discussed.

5.4.1 ZnO NP induce DNA double strand breaks

The *in vitro* genotoxicity of two different sizes of ZnO NP (4-5 nm, 15-18 nm), ZnO bulk as well as ZnCl₂ was investigated. The cells were also pretreated with NAC scavenging ROS, DTPA complexing dissociated Zn²⁺, and particle coating with BSA reducing dissociation. The treatment with ZnO NP (15-18 nm) resulted in a strong DNA damaging of A549 cells within 15 min of exposure, while strong intracellular increased Zn²⁺ and marginal ROS-levels were observed, suggesting that ZnO NP could trigger DNA damages. Furthermore we observed as well DNA DSB in primary cells of mucosa after treatment with ZnO NP (15-18 nm). The treatment with ZnO NP (4-5 nm) also leads to strong increased DNA damages in A549 cells within 15 min, while lesser intracellular Zn²⁺-levels and slight ROS-levels were detected. Comparable to our results of treatment with ZnO NP (15-18 nm), several investigations showed a concentration-dependent enhanced generation of ROS and DNA damages in different cell lines after ZnO NP treatment using 60-70 µg/mL as highest concentration in contrast to our final concentration of 100 µg/mL^{136,152,240,268}. Moreover, DNA damages have been shown to occur after repetitive exposure to low concentrations of ZnO NP³⁰⁰. Generation of ROS is often used to explain toxic and especially genotoxic responses to ZnO NP, after overwhelming intracellular ROS detoxification pathways^{172,187,301,187,302-304}. *Karlsson et al. (2014)* observed oxidative distress as the main genotoxic product in A549 cells, after exposure to ZnO NP for 4 h³⁰⁵. In our study the scavenging of ROS by NAC resulted in an incomplete inhibition of DNA DSB after treatment with ZnO NP of both sizes. *Karlsson et al. (2014)* observed DNA DSB after 4 h of treatment with 20 µg/mL ZnO NP in contrast to our observed early generation of DNA DSB after treatment with 100 µg/mL³⁰⁵. Furthermore, we observed ROS, in case of ZnO NP (15-18 nm) after 30 min and just a slight increase after ZnO NP (4-5 nm) exposure, suggesting ROS as minor harmful factor in the early event of DNA damage. Furthermore we found DNA damages after treatment with ZnO bulk material. Bulk material is in the size of micrometer. Usually, the toxicity of nanoparticles is associated with their enhanced

reactivity due to their increased surface area to volume ratio. It is larger and thus has a reduced reactivity compared to nanoparticles. Nevertheless, we observed DNA DSB induced by ZnO bulk material. This genotoxic potential of ZnO bulk material could also be an effect of Zn^{2+} dissociation from the material. To analyze if Zn^{2+} is the more decisive damaging mechanism we pretreated the cells with DTPA. Complexation of Zn^{2+} by DTPA resulted in a complete inhibition of DNA DSB in case of ZnO NP (15-18 nm) treatment. We therefore recommend that the DNA damages are directly attributed to Zn^{2+} , by an unknown mechanism of Zn^{2+} -DNA-interaction. We found a strong accumulation of Zn^{2+} in the nucleus, after ZnO NP and $ZnCl_2$ treatment (see Figure 27). The Zn^{2+} ions possibly interact directly with negatively charged phosphates of the DNA backbone. However, the early peak of DNA damage (1 min after $ZnCl_2$ and 15 min after ZnO NP treatment) could be explained by dissociated particles. Generally under physiological conditions, most of Zn^{2+} is bound to proteins, such as MT. Enhanced levels of ROS may oxidize the zinc binding thiol groups of MT, which lead to the release of MT-bound Zn^{2+} reducing the puffer capacity and in turn reinforcing the DNA damaging capability of free Zn^{2+} ³⁰⁶. Especially the second peak of DNA DSB could be attributed to increased ROS-levels, measured after 30 min and thereafter increased Zn^{2+} concentrations. Looking at all observations together, we suggest that DNA damages are related to two different mechanisms. The first peak is directly related to the internalized Zn^{2+} , taking place in the first minutes after ZnO NP exposure and minor to the involvement of generated ROS. The second peak is related to the induced ROS and thereafter increased Zn^{2+} concentrations. The nuclear Zn^{2+} could interact with the DNA by intercalation in the helix, or as already mentioned before, react with the phosphates in the DNA backbone.

5.4.2 Activation of DNA damage response

In this study, we observed an early and late induction of DNA DSB, after ZnO NP and $ZnCl_2$ exposure. The fast generation of DNA DSB, as well as the fast intracellular uptake of Zn^{2+} , in comparison to later generation of ROS, suggests Zn^{2+} as main mechanism behind ZnO NP genotoxicity. Therefore, we analyzed the DNA damage response activation of two well known pathways after ZnO NP treatment: ATM/Chk2- and ATR/Chk1 signaling. The ATM/Chk2 signaling was activated following cell exposure to ZnO NP as well as $ZnCl_2$. Regardless, no activation of ATR/Chk1 signaling was observed. These data show that the ZnO NP induced DNA DSB activated the DDR by ATM/Chk2- and not by ATM/Chk1 signaling. *Setyawati et al. (2015)* observed ATM, ATR and Chk1 activation leading to cell cycle arrest or apoptosis in presence of ZnO NP. They discussed their outcomes as mainly mediated by ROS, but they implicated Zn^{2+} as

5 Discussion

an alternative regulator³⁰⁷. The autophosphorylation of ATM at Ser1981 is still known as sensitive marker for DNA DSB and a key process representing cellular responses to DNA damages^{308,309}, while ATR is mainly activated in presence of DNA SSB. Therefore, we suggested that the activation of ATM/Chk2 pathway is mediated by the generated DNA DSB which are observed in this study. After ATM phosphorylation we observed increased phosphorylation levels of the downstream effector proteins, Chk2, p53 and p21 after treatment with ZnO NP and ZnCl₂. Previously, we showed that ZnO NP, as well as ZnCl₂, induce DNA DSB in a biphasic way. We further investigated whether ZnO NP induce ATM/Chk2 activation through Zn²⁺ or ROS. The extracellular complexation of Zn²⁺ by DTPA resulted in a total inhibition of DNA DSB and an inactivation of ATM/Chk2 signaling. In contrast, scavenging of ROS led to no complete inhibition of DNA DSB and the ATM/Chk2 signaling is activated. We suggested that these outcomes further confirmed Zn²⁺ as the basic mechanism of ZnO NP genotoxicity. Chk2 is located downstream of ATM and is activated in an ATM-dependent manner after DNA damages. Chk2 is activated in response to ZnO NP, while DTPA pretreatment resulted in a Chk2 inhibition and NAC treatment in no inhibition, confirming again the activation of ATM/Chk2 signaling mediated by dissociated Zn²⁺. P53 is stabilized by a variety of stress related signals. Subsequently, the tumorsuppressor p53 accumulates in the nucleus, binds in a specific way to DNA and regulates the transcription of several downstream effector genes³¹⁰. In case of DNA damage, ATM induces different p53 modifications, resulting in two well investigated main consequences: the cell cycle arrest with induction of DNA repair or apoptosis. We observed a strong stabilization of p53 in presence of ZnO NP and ZnCl₂, as consequence of DNA damage, after 4 h. This strong p53 stabilization was reported before by Meyer *et al.* (2011) in human fibroblasts using same exposure time and concentration³¹¹. Hainout *et al.* (2001) described two ways of p53 activation in presence of ROS. P53 is activated after ROS induced DNA damages through AMT/Chk2 signaling or hypoxia³¹⁰. The second possibility requires an interaction of hypoxia inducible factor (HIF-1 α) and p53 but the detailed mechanism is still less understood³¹⁰. Chandel *et al.* (2000) postulated that the mitochondrial generation of ROS regulates the redox state of cytoplasm and is responsible for p53 stabilization in presence of hypoxia³¹². In case of ZnO NP (15-18 nm), we observed a time-dependent increase of ROS while $\Delta\Psi_m$ depolarized, but no ROS-dependent activation of p53 was observed. These findings suggested that the activation of p53 after particle treatment is independent of ROS. Furthermore, the p53 protein contains cysteins localized within the DNA binding domain. Three of these cysteins and a histidin are needed to coordinate the zinc building a protein structure that interacts directly to DNA^{310,311,313,314}. Metal chelation experiments from Méplan *et al.* (2000) reported, that p53 is dependent on Zn²⁺

coordination to bind specifically to DNA, as well as for a correct protein folding^{310,314}. *Hainaut et al. (2001)* reported that the p53 zinc-binding activity is regulated by MT. High levels of MT operate as chelator for Zn²⁺ resulting in the prevention of p53 folding to an active form³¹⁰. Interestingly, beside the p53 activation by ZnO NP and ZnCl₂ treatment we found a total inhibition of p53 after complexing Zn²⁺ by DTPA, suggesting Zn²⁺ as mediator of p53 stabilization in presence of DNA DSB. P53 activates the p21 gene, which suppresses the cell cycle phase. Another possibility for p21 activation is the accumulation of p16 in presence of DNA damages. P21 is a cyclin-dependent kinase inhibitor and known as a transcriptional target of p53. It triggers the degradation of cyclin B1 mediating the G2/M cell-cycle arrest^{315,316}. We found that p21 was highly activated in ZnO NP treated cells after 4 h, suggesting that p21 activation has been triggered by the approved p53 signaling pathway. *Setyawati et al. (2015)* showed a p53 independent activation of p21 in carcinogenic epithelial cells, while p21 activation is triggered by p53 after ZnO NP treatment of normal epithelial cells³⁰⁷. They further hypothesized p21 activation as consequence of Erk-mediated pathway activation. They based their hypothesis on zinc ions released from ZnO NP, because Zn²⁺ is known as transducer of EGFR-signaling^{293,308,317,307}. Interestingly, we found an activation of Erk and p21 after treatment with ZnO NP and ZnCl₂ in a Zn²⁺ dependent manner. Data reported by *Setyawati et al. (2015)* support our findings by observing a Zn²⁺ mediated activation of Erk and p21³⁰⁷. They suggested p21 as a second possible mediator besides p53. Concluding, we suggested an activation of ATM/Chk2 activation in a Zn²⁺ dependent manner after dissociation from the particles.

6 Conclusion and Outlook

The combination of physico-chemical characteristics, as found in ZnO nanoparticles, allows interactions with cells and opens up new research directions for medicine, industrial product design, and environmental remediation. Besides these excellent properties for future industrial applications the risk of possible harmful side effects is important to investigate. In this context we showed that ZnO NP exposure to cells results in toxic effects with reduced viability, decreased $\Delta\Psi_m$, released ROS, initiation of apoptosis and considerably increased DNA damages in form of DNA DSB. We observed increased Zn^{2+} levels in cytoplasm, nucleus and mitochondria but rarely detectable ZnO NP. We found evidence for the assumption that Zn^{2+} intake is the initial step of ZnO NP intoxication rather than uptake of ZnO NP. We found increased ROS-levels after ZnO NP exposure, but strongly reduced ROS-levels after NAC treatment were not reflected in equivalently decreased levels of DNA DSB. This concept of Zn^{2+} rather than ROS mediated DNA damages are supported by our DNA damage response pathway analysis. We found ATM/Chk2, but no ATR/Chk1 pathway activation after ZnO NP exposure. This is indicative for DNA DSB recognition, but not DNA SSB frequently induced by ROS. Complexing of free Zn^{2+} resulted consequently in inhibited ATM/Chk2 activation, but NAC treatment resulted in no change of activation level. Taken together we suggest that the two phases of DNA damages are related to two different mechanisms: the first peak is related to the internalized Zn^{2+} taking place in the first minutes after the ZnO NP exposure and the second peak is related to the release of endogenous Zn^{2+} by increasing ROS-levels. Our data suggest a direct DNA damaging potential of Zn^{2+} by an unknown mechanism and ROS as a trigger of endogenous zinc release.

For this reasons further studies are now mandatory to decipher the mechanisms resulting in DNA damages. Especially the direct interactions of Zn^{2+} with DNA structure as well as the ROS triggered release of Zn^{2+} from intracellular proteins have to be investigated. The DNA damaging mechanism and possible mutagenic potential of ZnO NP have to be evaluated more detailed to reduce their hazardous health effects and optimize their physico-chemical characteristics for industrial application.

4 h	14.83	5.51	4.63	4.79

8.2 Stabilization of ZnO NP with BSA

Stabilization experiments are based on 3 independent experiments. For the statistical analysis the one-way analysis of variance (ANOVA) with Bonferroni's multiple comparison test was carried out to compare the group of control with ZnO NP, control with ZnO NP + BSA, ZnO NP with ZnO NP + BSA (* for $p < 0.05$ is significant, ** for $p < 0.01$ is highly significant, *** for $p < 0.001$ is extremely significant).

8.4 Nuclear Zn²⁺ accumulation

cLSM measurements of nuclear Zn²⁺ distribution are based on at least 3 independent experiments. The FluoZin™-3 intensity of at least, 2 cells per image was calculated by the use of Image J 1.47f. For the statistical analysis of nuclear Zn²⁺ accumulation after ZnO NP (4-5 nm), ZnO NP (15-18 nm), and ZnCl₂ treatment the one-way analysis of variance (ANOVA) with Bonferroni's multiple comparison test was carried out to compare the time points in each groups to the untreated control (* for p<0.05 is significant, ** for p<0.01 is highly significant, *** for p<0.001 is extremely significant).

8 Appendix

8.5 Viability

Spectrofluorimetric experiments of intracellular Zn²⁺ distribution are based on at least 3 independent experiments. For the statistical analysis of cellular viability after treatment with ZnO NP (0.1, 10 and 100 µg/mL) the one-way analysis of variance (ANOVA) with Bonferroni's multiple comparison test was carried out to compare all points in time within a group (* for p<0.05 is significant, ** for p<0.01 is highly significant, *** for p<0.001 is extremely significant).

8.6 ROS assay

Spectrofluorimetric measurements of intracellular ROS-levels are based on at least 3 independent experiments. For the statistical analysis the one-way analysis of variance (ANOVA) with Bonferroni's multiple comparison test was carried out to compare the group of ZnO NP with ZnCl₂, ZnO NP + BSA, ZnO NP + NAC and ZnO NP + DTPA (* for p<0.05 is significant, ** for p<0.01 is highly significant, *** for p<0.001 is extremely significant).

8.7 Mitochondrial membrane potential ($\Delta\Psi_m$)

Spectrofluorimetric measurements of mitochondrial membrane potential after treatment with ZnO NP (4-5 nm), ZnO NP (15-18 nm), and ZnCl₂ are based on at least 3 independent experiments. For the statistical analysis a one-way analysis of variance (ANOVA) with Bonferroni's multiple comparison test was carried out to compare the group of ZnO NP (15-18 nm) to the groups of ZnO NP (4-5 nm) and ZnCl₂ (* for p<0.05 is significant, ** for p<0.01 is highly significant, *** for p<0.001 is extremely significant).

Declaration of the Authorship

I hereby declare that I wrote the dissertation submitted without any unauthorized external assistance and used only sources acknowledged in the work. All textual passages which are appropriated verbatim or paraphrased from published and unpublished texts as well as all information obtained from oral sources are duly indicated and listed in accordance with bibliographical rules. In carrying out this research, I complied with the rules of standard scientific practice as formulated in the statutes of Johannes Gutenberg-University Mainz to insure standard scientific practice.

Mainz, den 6. November 2015

Dipl. Biologin Julia Heim

Declaration

Here I declare that the scientific thesis I am handling in has not yet been published at any other German University, or any university abroad, or any comparable institution, with the aim of attaining a scientific degree.

Here I also declare that I have not yet finished any other doctoral PhD or any similar graduation program in any of the subjects represented by the MPGC-JOGU without success.

Mainz, den 6. November 2015

Dipl. Biologin Julia Heim
