To my family

*'Far better an approximate answer to the right question,
which is often vague,
than an exact answer to the wrong question,
which can always be made precise.'*

John W. Tukey

Notations and symbols

\in	Element of
\subset	Subset of
\equiv	Identically equals
\sim	Essentially equal to or equivalent
\dagger	Hermitian conjugate
f^+, A^+	Generalised solution and generalised inverse respectively
f'	First derivative of f
$\langle f \rangle$	Mean value of f
$\mathbf{x} = (x^j)$	Vector in Euclidean n -dimensional space \mathbb{R}^n . The components are labelled by latin letters ($j = 1, 2, 3$)
$\hat{\mathbf{x}} = \frac{\mathbf{x}}{ \mathbf{x} }$	Unit vector in the direction of \mathbf{x}
$x = (x^\mu)$	4-Vector in 4-dimensional Minkowski space. The components are labelled by greek letters ($\mu = 0, 1, 2, 3$)
$d^n x, d\mathbf{x}$	Volume element in Euclidean n -dimensional space \mathbb{R}^n
$d^4 x = dx^0 dx^1 dx^2 dx^3$	Volume element in 4-dimensional Minkowski space
I	Unit operator or matrix
$\bar{\Omega}$	Closure of the domain Ω
$\partial\Omega$	Boundary of the domain Ω
$O(E)$	Terms of order E
$\mathcal{N}(A)$	Null-space of operator A
$\mathcal{R}(A)$	Range of operator A
$\mathcal{D}(A)$	Domain of operator A
A^*	Adjoint of A
A^T	Transposed of A
$\text{Tr}A$	Trace of A
$ \cdot $	Absolute value
$\ \cdot\ _{\mathcal{X}}$	Norm defined on the space \mathcal{X}

$\text{Re } x$	Real part of x
$\text{Im } x$	Imaginary part of x
\mathbb{P}	Principal part
Σ	Summation
$[\mathcal{O}]$	Mass dimension of operator \mathcal{O} , i.e., $[\mathcal{O}] = M^{d(\mathcal{O})}$
$\mathcal{F}[f](x)$	Fourier transform of f
$(f, g)_{\mathcal{X}}$	Scalar product defined on the space \mathcal{X}
Δ	Laplace operator
∇	Nabla operator
$\delta(x)$	Dirac δ -function ($-\infty < x < \infty$); $\delta(x) = 0$ for $x \neq 0$, $\int_{-\infty}^{\infty} dx \delta(x) = 1$
$\theta(x)$	Heaviside-function ($-\infty < x < \infty$); $\theta(x) = 0$ for $x < 0$, $\theta(x) = 1$ for $x > 0$
$q_{\alpha}^i, \bar{q}_{\alpha}^i$	Quark fields. Flavours are labelled by latin letters, here i , and colours by greek letters, here α
$G_a^{\mu\nu}$	Gluon field strength tensor
γ^{μ}, γ_5	Dirac matrices
λ^a	Gell-Mann colour matrices
f_{abc}	Structure constant of $SU(3)$
$: A \cdot B \cdot \dots :$	Normal ordering of the operators A, B, \dots

Abbreviations

MC	Monte Carlo
LO	Leading order
NLO	Next-to-leading order
SVD	Singular value decomposition
QCD	Quantum chromodynamics
QED	Quantum electrodynamics
OPE	Operator product expansion
CKM	Cabibbo-Kobayashi-Maskawa
PCAC	Partial conservation of axial-vector current
EIT	Electrical impedance tomography
FEM	Finite element method
CL	Confidence level
LS	Least-squares
CR	Confidence region
p.d.f.	probability distribution function

Introduction

We call two problems *inverse* to each other if the formulation of each of them requires full or partial knowledge of the other. By this definition, it is obviously arbitrary which of the two problems we call the direct and which we call the inverse problem. But usually, one of the problems has been studied earlier and, perhaps, in more detail. This one is usually called the *direct* problem, whereas the other is the *inverse* problem. However, there is often another, more important difference between these two problems. Hadamard (see [Ha23]) introduced the concept of a *well-posed problem*, originating from the philosophy that the mathematical model of a physical problem has to have the properties of uniqueness, existence, and stability of the solution. If one of the properties fails to hold, he called the problem *ill-posed*. It turns out that many interesting and important inverse problems in science lead to ill-posed problems, while the corresponding direct problems are well-posed. Often, existence and uniqueness can be forced by enlarging or reducing the solution space (the space of “models”). For restoring stability, however, one has to change the topology of the space, which is in many cases impossible because of the presence of measurement errors. At first glance, it seems to be impossible to compute the solution of a problem numerically if the solution of the problem does not depend continuously on the data, i.e., for the case of ill-posed problems. Under additional *a priori* information about the solution, such as smoothness and bounds on the derivatives, however, it is possible to restore stability and construct efficient numerical algorithms.

The thesis contains three main parts. The aim of the first part is to introduce the basic notations and difficulties encountered with ill-posed problems and then study the basic properties of regularisation methods for linear ill-posed problems. In the second and third part we aim to find stable solutions to two inverse problems arising in different fields of physics.

The first is an inverse problem of quantum chromodynamics (QCD). QCD is widely considered to be a good candidate for a theory of the strong interactions. Asymptotic freedom allows us to perform a perturbative treatment of strong interactions at short distances. Long distance behaviour is not fully understood: it is commonly believed that, due to the nontrivial structure of the physical vacuum, the perturbation expansion does not completely define the theory and that one has to add non-perturbative effects as well. In order to make a comparison with experiment possible, even in the resonance energy range, Shifman, Vainshtein and Zakharov [SVZ79a] have proposed to use the Operator Product Expansion (OPE) and to introduce the vacuum expectation values of the operators occurring in the OPE, the so called *condensates*, as phenomenological parameters. The knowledge of

these parameters is useful for studying if one can indeed obtain a consistent description of the low energy hadronic physics and get more insight into the properties of the QCD vacuum. It is therefore important not only to determine the values of the condensates from experimental data, but also the accuracy of the determination, i.e. to determine their allowed range.

In QCD, perturbation expansions, together with some non-perturbative effects, allows us to approximate the two point functions of hadronic currents, i.e., vacuum expectation values of the time ordered product of two hadronic currents, in the distant space-like region in terms of a few parameters (the values of condensates). On the other hand, the discontinuity of these amplitudes in the time-like region is related to more directly measurable quantities. Although analyticity strongly correlates the values of the amplitudes in these two regions, the errors affecting both types of *data* make the correlation much looser. Any procedure aimed to build up acceptable amplitudes must take into account these errors in a reasonable way.

There are several methods, generically called *QCD sum rules*, dealing with this problem of analytic extrapolation [BB81a, BLR85, SVZ79a]. Most of them include the *theoretical errors* in the space-like region only at a qualitative level, and/or need (explicit and implicit) assumptions on the derivatives of the amplitudes. The application of fully controlled analytic extrapolation techniques should remedy these effects. There are a few methods of this sort, in which the error channels in the space-like region are defined through L^2 -norms [ASS07, CSSS04] or L^∞ -norms [AM89, ACM90, CM90].

The functional method we use [ASS07] allows us to extract within rather general assumptions the condensates from a comparison of the time-like experimental data with the asymptotic space-like results from theory. We will see that the price to be paid for the generality of assumptions is relatively large errors in the values of the extracted parameters. Although we do not claim that our method is superior to other approaches, we hope that our results lend additional confidence to the numerical results obtained with the help of methods based on QCD sum rules [BB81a, BB81b, Be81, Be88, BLR85, DS88, Io05, KPS84, LNT84, Na95, Na95, Na96, Na98, Na02, Na04, RRY85, SVZ79a, Yn99].

For the experimental data on the time-like region, one has more possibilities at hand. We have chosen to work with the final τ data provided by the ALEPH collaboration [ALEPH05], because they have the smallest experimental errors. One may also ask why τ -decays and not e^+e^- -annihilation? The answer lies in the fact that the physics of hadronic τ -decays has been the subject of much progress in the last decade, both at the experimental and theoretical level. Somewhat unexpectedly, hadronic τ -decays provide one of the most powerful testing grounds for QCD. This situation results from a number of favourable conditions:

- The τ lepton is heavy enough to decay into a variety of hadrons, with net strangeness 0 and ± 1 ;
- τ leptons are copiously produced in pairs at e^+e^- colliders, leading to simple event topologies with little background;

-
- Experimental studies of τ -decays could be performed with large data samples;
 - As a consequence, τ -decays are experimentally known to great detail and their rates measured with high precision;
 - The theoretical description of hadronic τ -decays is based on solid ground.

The second inverse problem we aimed to solve is in the field of Electrical Impedance Tomography (EIT). EIT is a technology developed to image the electrical conductivity distribution of a conductive medium. It is of interest because of its low cost and also because the electrical conductivity gives direct information about the internal composition of the conductive medium. The technique works by performing simultaneous measurements of direct or alternating electric currents and voltages on the boundary of an object. These are the data used by an image reconstruction algorithm to determine the electrical conductivity distribution within the object. This problem is also called the inverse conductivity problem and has applications as a method of industrial, geophysical and medical imaging.

It is well known that the inverse conductivity problem is a highly ill-posed, non-linear inverse problem and that the images produced are very sensitive to errors which can occur in practice. There has been much interest in determining the class of conductivity distributions that can be recovered from the boundary data, as well as in the development of related reconstruction algorithms. The interest in this problem has been generated by both difficult theoretical challenges and by the important medical, geophysical and industrial application of it. Much theoretical work has been related to the approach of Calderón concerning the bijection between the the conductivity inside the region and the Neumann-to-Dirichlet operator, which relates the distribution of the injected currents to the boundary values of the induced electrical potential [Ca80, KV85, Na88, SU88]. The reconstruction procedures that have been proposed include a wide range of iterative methods based on formulating the inverse problem as a nonlinear optimisation problem. These techniques are quite demanding computationally, particularly when addressing the three-dimensional problem. This drawback has encouraged the search for reconstruction algorithms which reduce the computational demands either by using some *a priori* information e.g. [BH00, BHV03, CFMV98] or by developing non-iterative procedures. Some of these methods [AHOS07, BH00, BHV03] use a factorisation approach while others are based on reformulating the inverse problem in terms of integral equations [CPSS00, CPS03, CPS04].

One of the approaches presented here is based on reformulating the inverse problem in terms of integral equations. A feature of this method is that many of the calculations involve analytical expressions containing the eigenfunctions of the kernel of these equations, the computational part being restricted to the introduction of the data, the numerical evaluation of some of the analytic formulæ and the solution of a final integral equation. The method consists in the determination of $Y(\mathbf{x}) = -\Delta\phi(\mathbf{x})$, in the sense of a generalised solution of inverse problems, by a single measurement of the potential $\phi(\mathbf{x})$, and its normal derivative on the boundary of the domain. The result $Y(\mathbf{x})$ can either be used directly to obtain rough

information on the conductivity or may be processed further to determine the conductivity by solving a first order partial differential equation. This can be done in a straightforward way by using the method of characteristics. We have applied this method for a two-dimensional domain, the unit disc, with no a priori information. However, since the problem is ill-posed, one needs to regularise it, i.e., search for approximate solutions satisfying additional constraints suggested by the physics of the problem. In our case we have used as a regularisation algorithm the truncated singular value decomposition. Unfortunately, the information gained on $Y(\mathbf{x})$, and the conductivity respectively, is restricted to their angular dependence (no radial information is present). One can hope that using some a priori information could improve the reconstruction.

Also an algorithm based on linearisation will be discussed. The aim of the algorithm is to perform reconstructions based on real data measured by the tomograph constructed in collaboration with Dr. K.H. Georgi and N. Schuster. For this, a belt of electrodes was placed around the chest of a human volunteer, voltages applied and currents measured. An important result of this algorithm is that the low conductivity (lungs) and high conductivity (heart) regions are well reconstructed. This is important for monitoring for lung problems such as accumulating fluid or a collapsed lung.

The EIT research is still active. There are about 30 groups worldwide who are actively performing research and it is still seen as an exciting area of medical physics. However, EIT has not yet made the transition from an exciting medical physics discipline into wide spread routine clinical use. The technique still needs to break into widespread clinical acceptance and effort is continuing actively into the clinical trials and pilot studies which will achieve this. Technical advantages may allow us to obtain more accurate tissue characterisation and image quality and this will undoubtedly help to advance clinical acceptance.

Outline of the thesis

As already stated, the first part of the thesis is an introduction to the basic concepts of inverse and ill-posed problems. The aim of the thesis is not to study inverse problems in general so that this part is just a general introduction collected from literature [Ba87, BB98, Be86, PS92, Lo89]. In the first chapter one can find the definitions of inverse and ill-posed problems, together with a few examples. Chapter 2 presents some regularisation methods of ill-posed problems. First, the generalised solution of inverse problems is presented and then Tikhonov's regularisation method and the truncated singular value decomposition are considered.

The second part of the thesis is concerned with an inverse problem in QCD: the determination of QCD condensates from τ -decay data. Here, we will start in Chapter 3 with a theoretical description of τ -decays: leptonic and hadronic decay width, hadronic polarisation function and its operator product expansion, and the dispersion relation satisfied by the polarisation function. This chapter represents the theory underlying the method we'll use to extract values for the condensates.

The experimental description of τ -decays is discussed in Chapter 4. In Chapter 5 we present a functional approach which allows us to extract within rather general assumptions values for the condensates from a comparison of the time-like τ -decay experimental data measured by the ALEPH Collaboration at LEP, with the asymptotic space-like QCD prediction. Results for condensates of dimension $d = 4, 6, 8$ and correlations between them for the $V - A$ and $V, A, V + A$ channels are presented in Chapters 6 and 7 respectively.

The third part of the thesis is concerned with the inverse conductivity problem. In Chapter 8 we present the technique of EIT and its practical applications in medicine, industry and geophysics as well as a history of the problem. In Chapter 9 we formulate the forward problem and aim to solve it by means of finite elements. Two reconstruction algorithms are discussed in Chapter 10. The first is based on reformulating the problem in terms of integral equations and aim to perform the reconstruction from a single set of measurements, while the latter is a linearisation type of algorithm which uses more sets of measurements. The second algorithm was also used on real data in Chapter 11, where reconstructions of a phantom immersed in a test tank filled with a conducting liquid are presented. Also measurements on the chest of a human object were taken and reconstructions performed with the aim of monitoring the lungs.

There are also 4 appendices which contain supplementary mathematical informations. In Appendix A we present the basic concepts of the theory of linear integral equations. In Appendix B we give the definition of Green's functions and we illustrate how they can be used to reduce the differential equations to integral ones. Appendix C presents the singular value decomposition method for integral operators. And last, in Appendix D, some basic concepts of statistics are presented: least-squares parameter estimation, confidence regions and the χ^2 test of goodness-of-fit.

Inverse problems

Inverse and ill-posed problems

Inverse problems of mathematical physics may be broadly described as problems of determining the internal structure or past state of a system from indirect measurements. Such problems would include for example the determination of diffusivities, conductivities, densities, sources, geometry of scatterers and absorbers and prior temperature distributions, to name just a few typical applications. Only recently a systematic treatment of such problems begun to emerge. The past few decades have witnessed a remarkable growth in inverse problems [Sa00].

Inverse problems most often do not fulfil Hadamard's principle of well-posedness: they might not have a solution in the strict sense, solutions might not be unique and/or might not depend continuously on data. Hence their mathematical analysis is subtle. The belief of Hadamard that problems motivated by physical reality should be well-posed is essentially generated by physics of the nineteenth century. The requirements of existence, uniqueness and continuity of the solution are deeply inherent in the idea of a unique, complete and stable determination of the physical events. As a consequence of this point of view, ill-posed problems were considered, for many years, as mathematical anomalies and were not seriously investigated. The discovery of the ill-posedness of inverse problems has completely modified this conception.

1.1 Inverse problems

Suppose that we have a mathematical model of a physical process. We assume that this model gives a description of the system behind the process and its operating conditions and explains the principal quantities of the model (see Fig.1.1): input, system parameters, output.

In most cases the description of the system is given in terms of a set of equations (ordinary and/or partial differential equations, integral equations,...), containing certain parameters.

The analysis of a given physical process via the mathematical model may be separated into three distinct types of problems.

- (A) The *direct problem*: Given the input and the system parameters, find out the output of the model.
- (B) The *reconstruction problem*: Given the system parameters and the output, find out which input has led to this output.

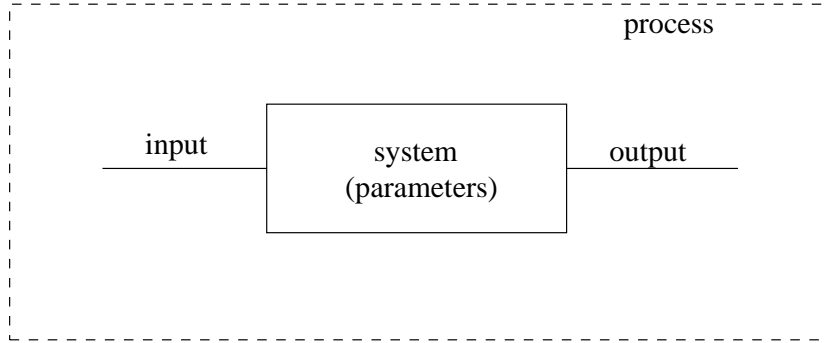

Figure 1.1: Mathematical model of a physical process.

- (C) The *identification problem*: Given the input and the output, determine the system parameters which are in agreement with the relation between input and output.

We call a problem of type (A) a *direct* (or *forward*) problem since it is oriented along a cause-effect sequence. In this sense problems of type (B) and (C) are called *inverse* problems because they are problems of finding out unknown causes of known consequences. It is immediately clear that the solution of one of the problems above involves a treatment also of the other problems.

We give a mathematical description of the input, the output and the system in functional analytic terms.

\mathcal{X} space of input quantities;

\mathcal{Y} space of output quantities;

\mathcal{P} space of system parameters;

$A(p)$ operator from \mathcal{X} into \mathcal{Y} associated to $p \in \mathcal{P}$.

In these terms we may reformulate the problems above in the following way:

(A) Given $f \in \mathcal{X}$ and $p \in \mathcal{P}$, find $g = A(p)f$.

(B) Given $g \in \mathcal{Y}$ and $p \in \mathcal{P}$, solve the equation

$$Af = g \quad (f \in \mathcal{X}) \tag{1.1}$$

where $A = A(p)$.

(C) Given $g \in \mathcal{Y}$ and $f \in \mathcal{X}$, find $p \in \mathcal{P}$ such that

$$A(p)f = g. \tag{1.2}$$

At first glance, the direct problem seems to be solved much more easier than the inverse problems. However, for the computation of $g = A(p)f$ it may be necessary to solve a differential or integral equation, a task which may be of the same complexity as the solution of the equations in the inverse problem.

In certain simple examples inverse problems can be converted formally into a direct problem. For example, if A has a known inverse then the reconstruction problem is solved by $f = A^{-1}g$. However, the explicit determination of the inverse does not help if the output y is not in the domain of definition of A^{-1} . This situation is typical in applications due to the fact that the output may be only imprecisely known and/or distorted by noise.

As we stated above, a direct problem is a problem oriented along a cause-effect sequence; it is also very often a problem directed towards a loss of information: its solution defines a transition from a physical quantity with a certain information content to another quantity with smaller information content. In general it implies that the solution is much smoother than the data: the image provided by a band-limited system is smoother than the corresponding object, the scattered wave due to an obstacle is smooth even if the obstacle is rough, and so on. A more rigorous description of the loss of information typical for direct problems can be found in Section 1.3.

The conceptual difficulty common to most inverse problems is that by solving these problems, we would like to accomplish a transformation which should correspond to a gain of information. This provides the explanation of a typical mathematical property of inverse problems which is known as ill-posedness.

1.2 Some examples of inverse problems

Inverse problems fall mainly into three different but intimately related categories:

- Inverse scattering problems,
- Inverse boundary value problems,
- Inverse spectral problems.

In the early 90's, the active research carried out in the field of inverse problems has brought a lot of new insight into the deeper nature of these problems and especially to the interrelation between them. In the following, we describe and discuss briefly the main features of each of these classes, give examples and further references.

Inverse scattering problems

Inverse scattering problems form undoubtedly one of the most studied set of inverse problems. The setting is the following: Far away from the target having unknown physical properties, a wave field is sent in. It is assumed that the interaction mechanism of the wave field with the target is qualitatively known. The scattered field

is measured, and from this data one attempts to reconstruct the properties of the scatterer.

A classical example of inverse scattering problems arises in quantum mechanics. Assume that we have a scattering potential q in \mathbb{R}^3 . The quantum mechanical scattering with fixed energy $E = k^2$, $k > 0$ ($\hbar = c = 1$), is described by the Schrödinger equation

$$(-\Delta - k^2 + q(\mathbf{x}))\psi(\mathbf{x}) = 0. \quad (1.3)$$

The potential q should decrease fast enough as \mathbf{x} tends to infinity. The typical assumption about the field ψ is that it is a superposition of the incoming plane wave and the scattered radiation field satisfying Sommerfeld's radiation condition at infinity, i.e.,

$$\psi(\mathbf{x}) = e^{ik\boldsymbol{\theta}\cdot\mathbf{x}} + \psi_{\text{sc}}(\mathbf{x}), \quad (1.4)$$

where

$$\lim_{|\mathbf{x}| \rightarrow \infty} |\mathbf{x}|(\hat{\mathbf{x}} \cdot \nabla - ik)\psi_{\text{sc}}(\mathbf{x}) = 0. \quad (1.5)$$

An equivalent way of formulating the radiation condition (1.5) is to assume that

$$\psi_{\text{sc}}(\mathbf{x}) = \frac{e^{ik|\mathbf{x}|}}{|\mathbf{x}|} A(\hat{\mathbf{x}}, \boldsymbol{\theta}, k) + O\left(\frac{1}{|\mathbf{x}|^2}\right). \quad (1.6)$$

The function $A(\hat{\mathbf{x}}, \boldsymbol{\theta}, k)$ is called the scattering amplitude, and it is related to the scattering potential and the scattered field through

$$A(\hat{\mathbf{x}}, \boldsymbol{\theta}, k) = -\frac{1}{4\pi} \int_{\mathbb{R}^3} e^{-ik\hat{\mathbf{x}}\cdot\mathbf{y}} q(\mathbf{y})\psi(\mathbf{y})d^3y. \quad (1.7)$$

Depending on the type of measurements, one can now pose different inverse scattering problems, of which we list the following:

- Reconstruct the potential from the knowledge of the scattering amplitude at any energy

$$\{A(\hat{\mathbf{x}}, \boldsymbol{\theta}, k) \mid \hat{\mathbf{x}}, \boldsymbol{\theta} \in S^2, k \in \mathbb{R}_+\}; \quad (1.8)$$

- Reconstruct the potential from the knowledge of the scattering amplitude at fixed energy

$$\{A(\hat{\mathbf{x}}, \boldsymbol{\theta}, k) \mid \hat{\mathbf{x}}, \boldsymbol{\theta} \in S^2\}, k > 0 \text{ fixed}; \quad (1.9)$$

- Reconstruct the potential from the knowledge of the backscattering amplitude at any energy

$$\{A(-\boldsymbol{\theta}, \boldsymbol{\theta}, k) \mid \boldsymbol{\theta} \in S^2, k \in \mathbb{R}_+\}. \quad (1.10)$$

The first one of the above inverse problems is the most classical one. It is formally over-determined in the sense that the data set is indexed over a five dimensional space $S^2 \times S^2 \times \mathbb{R}_+$, while the unknown function q is over a three-dimensional space. Based on this over-determinacy, there is a rather simple way of seeing the uniqueness of the solution to this problem. Indeed, one can show that the scattering solution ψ to (1.3) behaves as

$$\psi(\mathbf{x}) = e^{ik\boldsymbol{\theta}\cdot\mathbf{x}} + \mathcal{O}\left(\frac{1}{k}\right), \quad \text{as } k \rightarrow \infty. \quad (1.11)$$

Therefore, if we choose $\boldsymbol{\xi} \in \mathbb{R}^3$ and let k tend to infinity while keeping the vector $k(\boldsymbol{\theta} - \mathbf{x}) = \boldsymbol{\xi}$ fixed, we find that

$$\lim_{\substack{k \rightarrow \infty \\ k(\boldsymbol{\theta} - \mathbf{x}) = \boldsymbol{\xi}}} A(\hat{\mathbf{x}}, \boldsymbol{\theta}, k) = \mathcal{F}[q](\boldsymbol{\xi}), \quad (1.12)$$

i.e., the scattering amplitude tends towards the Fourier transform of the potential. Therefore, the data of the problem determine the potential q uniquely.

For the second problem posted, the over-determinacy of the data is one dimension less and consequently the problem to show the uniqueness of the solution is more difficult. As for the third one (called the inverse backscattering problem) we may mention that there are still open problems related to the uniqueness of the solution and reconstruction of the potential.

Another classical, very important and closely related type of inverse scattering problems deals with obstacle scattering. A typical inverse obstacle scattering can be formulated as follows: Assume that in \mathbb{R}^3 , there is an obstacle Ω , whose shape one tries to recover from far field measurements. Assume that the medium outside the obstacle is governed by the equations of linear acoustics, i.e., the pressure field u satisfies the Helmholtz equation

$$\Delta u(\mathbf{x}) + k^2 u(\mathbf{x}) = 0, \quad \mathbf{x} \in \mathbb{R}^3 / \bar{\Omega}. \quad (1.13)$$

The pressure field is assumed to satisfy a boundary condition at $\partial\Omega$, typically the Dirichlet (“soft sound”), Neumann (“hard sound”) or a mixed (“impedance”) condition. For penetrable obstacles, the appropriate boundary condition is a transmission condition. Again, one probes the target by sending in an initial field u_0 , and the interacting total field is

$$u(\mathbf{x}) = u_0(\mathbf{x}) + u_{\text{sc}}(\mathbf{x}), \quad (1.14)$$

where the scattered field satisfies the outgoing radiation condition (1.5), or

$$u_{\text{sc}}(\mathbf{x}) = \frac{e^{ik|\mathbf{x}|}}{|\mathbf{x}|} u_{\infty}(\hat{\mathbf{x}}) + \mathcal{O}\left(\frac{1}{|\mathbf{x}|^2}\right), \quad (1.15)$$

the function u_{∞} being the far pattern of the field which corresponds to the scattering amplitude here. The inverse scattering problem now consists in reconstructing the shape of the object from the far field patterns generated by a set of incoming fields.

Besides the acoustic inverse obstacle scattering, one can look at the similar problem when the unknown target is illuminated with electromagnetic radiation. Since the electromagnetic fields satisfy the Helmholtz equation in vacuum, the transition from acoustics to electromagnetism does not seem so large. The boundary conditions, however, have vectorial nature and the field components will be coupled.

Inverse boundary value problems

Let us move now to the second large area of inverse problems, the inverse boundary value problems. The change in the setting when moving from inverse scattering problems to inverse boundary value problems is by no means sharp. Again, one has an object with unknown physical parameters and the objective is to find out these parameters in a non-invasive way.

Let us start with a concrete example of impedance tomography: We ask whether it is possible to make an image of the internal electromagnetic structure of a body (e.g. human body) by injecting electric currents into the body and measuring the voltages needed to maintain the current. In practice, one attaches a number of electrodes on the surface of the body and measures the voltages needed to maintain the current configuration. By the linearity of the governing equations, dependence of the voltages on the currents is linear, so effectively the boundary data consists of a linear boundary map (or a matrix for the discretized version of the problem).

The governing equation for the potential u in the body Ω is simply the equation of continuity for the current $\mathbf{j} = \sigma \nabla u$:

$$\nabla \cdot \sigma \nabla u(\mathbf{x}) = 0, \quad \mathbf{x} \in \Omega, \quad (1.16)$$

where $\sigma(\mathbf{x}) > 0$ is the conductivity distribution, assumed to be a scalar function of \mathbf{x} . The current density through the boundary of the body is

$$j(\mathbf{x}) = \sigma(\mathbf{x}) \frac{\partial u}{\partial n}(\mathbf{x}) \Big|_{\partial\Omega}. \quad (1.17)$$

Assuming that the current density j is specified, one can solve the Neumann problem (1.16 - 1.17). In this way, one gets a complete collection of pairs

$$\{(j, u|_{\partial\Omega}) \mid u \text{ satisfies (1.16 - 1.17)}\}, \quad (1.18)$$

or, equivalently, one knows the Neumann-to-Dirichlet boundary map

$$\Lambda : \sigma \frac{\partial u}{\partial n} \Big|_{\partial\Omega} \rightarrow u|_{\partial\Omega}. \quad (1.19)$$

The inverse problem is to reconstruct σ in Ω from the knowledge of Λ .

The close connection with the inverse scattering problems becomes more obvious if we modify Eq.(1.16) slightly. Let us introduce the function ψ defined as

$$\psi(\mathbf{x}) = \sigma(\mathbf{x})^{1/2} u(\mathbf{x}). \quad (1.20)$$

One can show that Eq.(1.16) can be rewritten for ψ as

$$(\Delta - q)\psi = 0, \text{ where } q = \frac{\Delta\sigma^{1/2}}{\sigma^{1/2}}. \quad (1.21)$$

Thus, we are back to the Schrödinger equation with zero energy.

As the discussion shows, there is a strong interrelation between the inverse scattering and inverse boundary value problems. In many cases they can be shown to be equivalent: The knowledge of the boundary map determines the far field data uniquely and vice versa.

Inverse boundary value problems get considerably more complicated if one allows for anisotropies in the medium. In fact, there are known limitations on the uniqueness for anisotropic inverse problems while the corresponding isotropic problems allow a unique solution. As an example, consider the anisotropic counterpart of Eq.(1.16),

$$\sum_{i,j=1}^n \frac{\partial}{\partial x_i} \sigma^{i,j} \frac{\partial}{\partial x_j} u = 0, \text{ in } \Omega \in \mathbb{R}^n, \quad (1.22)$$

the potential u satisfying the boundary condition

$$\sigma^{i,j} \frac{\partial u}{\partial x_j} \Big|_{\partial\Omega} = g^i. \quad (1.23)$$

These equations can be written in coordinate free form using differential forms as

$$d\sigma du = 0 \text{ in } \Omega, \quad (1.24)$$

$$(\sigma du)|_{\partial\Omega} = g. \quad (1.25)$$

From this formulation, it can be shown that one can transform σ by a diffeomorphism that leaves the boundary $\partial\Omega$ untouched without affecting the boundary data. The question whether this is the only limitation on uniqueness is still open.

Inverse spectral problems

In the inverse spectral problems the input is the spectrum of an operator and one wishes to determine an unknown parameter of the operator. A classical example, also one of the simplest inverse problems in pure mathematics, is the one formulated by Mark Kac: “*Can one hear the shape of the drum?*” [Ka66]. Mathematically, the question is formulated as follows: Let Ω be a simply connected, plane domain (the drumhead) bounded by a smooth curve γ , and consider the wave equation for $u(x, t)$ (the displacement of the drumhead) on Ω with a Dirichlet boundary condition on γ (the drumhead is clamped at the boundary):

$$\Delta u(x, t) = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}(x, t) \text{ in } \Omega, \quad (1.26)$$

$$u(x, t) = 0 \text{ on } \gamma.$$

Looking for solutions of the form $u(x, t) = \operatorname{Re} e^{i\omega t} v(x)$ (normal modes) leads to an eigenvalue problem for the Dirichlet Laplacian on Ω :

$$\begin{aligned} \Delta v(x) + \lambda v(x) &= 0 \quad \text{in } \Omega, \\ v(x) &= 0 \quad \text{on } \gamma, \end{aligned} \tag{1.27}$$

where $\lambda = \omega^2/c^2$. Kac's question means the following: is it possible to distinguish "drums" Ω_1 and Ω_2 with distinct bounding curves γ_1 and γ_2 , simply by "hearing" all of the eigenvalues of the Dirichlet Laplacian?

Kac has showed that the asymptotic behaviour of λ_k (the resonance frequencies) at large k yields the volume and the total scalar curvature of Ω or the length of γ [Ka66]. This kind of inverse problem has not been given real data applications, but, in some way, it is the pillars of the so-called *geometric scattering theory*.

1.3 Ill-posed problems

In the previous section we mentioned that a typical property of inverse problems is ill-posedness, a property which is opposite to that of well-posedness.

The basic concept of a well-posed problem was introduced by the French mathematician Jacques Hadamard in a paper published in 1902 on boundary-value problems for partial differential equations and their physical interpretation [Ha1902]. In this first formulation, a problem is called well-posed when its solution is unique and exists for arbitrary data. In subsequent work Hadamard emphasises the requirement of continuous dependence of the solution on the data [Ha23], claiming that a solution which varies considerably for a small variation of the data is not really a solution in the physical sense. Indeed, since the physical data are never known exactly, this should imply that the solution is not known at all.

From an analysis of several cases Hadamard concludes that only problems motivated by physical reality are well-posed. An example is provided by the initial value problem for the D'Alembert equation which is fundamental in the description of wave propagation

$$\frac{\partial^2 u}{\partial x^2}(x, t) - \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}(x, t) = 0, \tag{1.28}$$

where c is the wave velocity. If we consider, for instance, the following Cauchy initial data at $t = 0$

$$u(x, 0) = f(x), \quad \frac{\partial u}{\partial t}(x, 0) = 0, \tag{1.29}$$

then there exists a unique solution given by

$$u(x, t) = \frac{1}{2} [f(x - ct) + f(x + ct)]. \tag{1.30}$$

This is a solution for any continuous function $f(x)$. Moreover it is obvious that a small variation of $f(x)$ produces a small variation of $u(x, t)$.

The previous problem is well-posed and, of course, basic in the description of physical phenomena. It is an example of a direct problem. An impressive example of an ill-posed problem and, in particular, of a non-continuous dependence on the data, was also provided by Hadamard [Ha23]. This problem which, at that time, was deprived of a physical motivation, is the Laplace equation in two variables

$$\frac{\partial^2 u}{\partial x^2}(x, y) + \frac{\partial^2 u}{\partial y^2}(x, y) = 0. \quad (1.31)$$

If we consider the following Cauchy initial conditions at $y = 0$

$$u(x, 0) = \frac{1}{n} \cos(nx), \quad \frac{\partial u}{\partial y}(x, 0) = 0, \quad (1.32)$$

then the unique solution is given by

$$u(x, y) = \frac{1}{n} \cos(nx) \cosh(ny). \quad (1.33)$$

The factor $\cos(nx)$ produces an oscillation of the surface representing the solution of the problem. This oscillation is imperceptible near $y = 0$ but becomes enormous at any given finite distance from the x -axis when n is sufficiently large. More precisely, when $n \rightarrow \infty$, the data of the problem tend to zero but, for any finite value of y , the solution tends to infinity.

This is now a classical example illustrating the effects produced by a non-continuous dependence of the solution on the data. If the oscillating function describes the experimental errors affecting the data of the problem then the error propagation from the data to the solution is described by Eq.(1.33) and its effect is so dramatic that the solution corresponding to real data is deprived of physical meaning. Moreover it is also possible to show that the solution does not exist for arbitrary data but only for data with specific analyticity properties.

A problem satisfying the requirements of existence, uniqueness and continuity is now called *well-posed* in the sense of Hadamard, even if the complete formulation in terms of the three requirements was first given by R. Courant [CH53b]. The problems which are not well-posed are called *ill-posed* or also *incorrectly posed* or *improperly posed*. Therefore an ill-posed problem is a problem whose solution is not unique or does not exist for arbitrary data or does not depend continuously on the data.

The previous observations and considerations can justify now the following general statement: A direct problem, i.e., a problem oriented along a cause-effect sequence, is well-posed while the corresponding inverse problem, which implies a reversal of the cause-effect sequence, is in general ill-posed. This statement, however, is meaningful only if we provide a suitable mathematical setting for the description of direct and inverse problems.

The first point is to define the class of objects to be imaged, which will be described by suitable functions with certain properties. In this class we also need a *distance*, in order to establish when two objects are close and when they are not.

In such a way our class of objects takes the structure of a *metric space* of functions. We denote this space by \mathcal{X} and we call it the *object space*.

The second point is to solve the direct problem, i.e. to compute, for each object, the corresponding image which can be called the computed image or the *noise-free image*. Since the direct problem is well-posed, to each object we associate one, and only one, image. As we already mentioned, this image may be rather smooth as a consequence of the fact that its information content is smaller than the information content of the corresponding object. This property of smoothness, however, may not be true for the measured images, also called *noisy images*, because they correspond to some noise-free image corrupted by the noise affecting the measurement process.

Therefore the third point is to define the class of the images in such a way that it contains both the noise-free and the noisy images. It is convenient to introduce a distance also in this class. We denote the corresponding function space by \mathcal{Y} and we call it the *image space*.

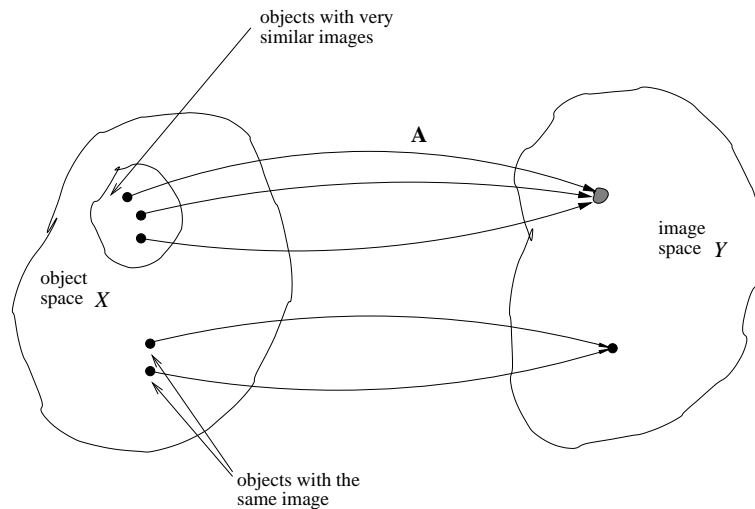

Figure 1.2: Schematic representation of the relationship between objects and images.

In conclusion, the solution of the direct problem defines a mapping (operator), denoted by A , which transforms any object of the space \mathcal{X} into a noise-free image of the space \mathcal{Y} . This operator is continuous, i.e. the images of two close objects are also close, because the direct problem is well-posed. The set of the noise-free images is usually called, in mathematics, the *range* of the operator A , and, as follows from our previous remark, this range does not coincide with the image space \mathcal{Y} because this space contains also the noisy images.

By means of this mathematical scheme it is possible to describe the loss of information which, as we said, is typical in the solution of the direct problem. It has two consequences. First, it may be possible that two, or even more, objects have exactly the same image. In the case of a linear operator this is related to the existence of objects whose image is exactly zero. These objects will be called

invisible objects. Then, given any object of the space \mathcal{X} , if we add to it an invisible object, we obtain a new object which has exactly the same image. Secondly, and this fact is much more general than the previous one, it may be possible that two very distant objects have images which are very close. In other words there exist very broad sets of distinct objects such that the corresponding sets of images are very small. All these properties are illustrated in Fig.1.2.

If we consider now the inverse problem, i.e. the problem of determining the objects corresponding to a given image, we find that this problem is ill-posed as a consequence of the loss of information intrinsic to the solution of the direct one. Indeed, if we have an image corresponding to two distinct objects, the solution of the inverse problem is not unique. If we have a noisy image, which is not in the range of the operator A , then the solution of the inverse problem does not exist. If we have two neighbouring images such that the corresponding objects are very distant, then the solution of the inverse problem does not depend continuously on the data.

1.4 A few examples of ill-posed problems

Fredholm integral equations of the first kind

A Fredholm integral equation of the first kind is an equation of the form

$$y(s) = \int_a^b K(s, t)x(t)dt, \quad (1.34)$$

where y is a given function (usually called the data), $K(\cdot, \cdot)$ is the kernel of the equation and the solution x is the unknown function which is sought. There are several observations concerning this equation. The first one is that the function y inherits some of the smoothness of the kernel K and therefore a solution may not exist if y is too roughly behaved. For example, if the kernel K is continuous and x is integrable, then the function y defined by Eq.(1.34) is also continuous and hence if the given function y is not continuous while the kernel is, then Eq.(1.34) can not have an integrable solution. Consequently, the question of existence of solutions is not trivial and requires more detailed knowledge of the properties of K .

Another point to be considered is the uniqueness of solutions. For example, if $K(s, t) = s \sin t$, then the function $x(t) = 1/2$ is a solution of

$$s = \int_0^\pi K(s, t)x(t)dt \quad (1.35)$$

but so is each of the functions $x_n(t) = 1/2 + \sin(nt)$, for $n = 1, 2, 3, \dots$

A more serious concern arises from the Riemann-Lebesgue lemma which states that if $K(\cdot, \cdot)$ is any square integrable kernel, then

$$\int_0^\pi K(s, t) \sin(nt)dt \rightarrow 0 \quad \text{as } n \rightarrow \infty. \quad (1.36)$$

From this it follows that if x is a solution of Eq.(1.34) and A is arbitrary, then

$$\int_0^\pi K(s, t) (x(t) + A \sin(nt)) dt \rightarrow y(s) \text{ as } n \rightarrow \infty. \quad (1.37)$$

Therefore for large values of n the slightly perturbed data

$$\tilde{y}(s) = y(s) + A \int_0^\pi K(s, t) \sin(nt) dt \quad (1.38)$$

corresponds to a solution $x(t) + A \sin(nt)$ which differs markedly from $x(t)$. Hence, for Fredholm equations of the first kind, solutions generally depend discontinuously upon the data.¹

Cauchy problem for the Laplace equation

The simplest example of ill-posed problems for the Laplace equation is a mixed boundary value problem in two dimensions. The problem is to determine in a rectangle $\{0 \leq x \leq \pi, 0 \leq y \leq y_0\}$ a function of two variables $u(x, y)$ satisfying the following conditions

$$\begin{aligned} \Delta u(x, y) &= 0, \\ u(0, y) &= u(\pi, y) = 0, \\ u(x, 0) &= f_0(x), \\ u_y(x, 0) &= f_1(x). \end{aligned} \quad (1.39)$$

The solution of the Laplace equation satisfying the homogeneous conditions on the edges of the strip can be represented in the form

$$u(x, y) = \sum_{k=1}^{\infty} (a_k e^{ky} + b_k e^{-ky}) \sin kx. \quad (1.40)$$

From the initial conditions one finds

$$a_k = \frac{1}{\pi} \left(\int_0^\pi f_0(x) \sin kx dx + \frac{1}{k} \int_0^\pi f_1(x) \sin kx dx \right), \quad (1.41)$$

$$b_k = \frac{1}{\pi} \left(\int_0^\pi f_0(x) \sin kx dx - \frac{1}{k} \int_0^\pi f_1(x) \sin kx dx \right). \quad (1.42)$$

Thus, the solution of the problem (1.39) is unique but its existence is not guaranteed and depends on the integrability properties of f_0 and f_1 and on the properties which $u(x, y)$ should have.

Let us now consider the following solutions of (1.39)

$$u_n(x, y) = a_n e^{ny} \sin nx. \quad (1.43)$$

¹For more details related to the solutions of the Fredholm integral equations of the first kind see Appendix A.

It is clear that the Cauchy data which lead to these solutions are:

$$f_{0n} = a_n \sin nx, \quad (1.44)$$

$$f_{1n} = na_n \sin nx. \quad (1.45)$$

Obviously, an appropriate choice of n and a_n may render these Cauchy data arbitrarily small in the norm², while the function u_n will be arbitrarily large for any fixed y .

Analytic continuation

There are several settings of the analytic continuation problem. We present here one classical example of analytic continuation for functions of a complex variable.

Let $f(z)$ be an analytic³ function of a complex variable, which is regular⁴ within a bounded region Ω on the complex plane and continuous in the closure $\bar{\Omega}$,

$$|f(z)| \leq c, \quad z \in \Omega. \quad (1.46)$$

Let $\partial\Omega$ be the boundary of Ω , Γ_1, Γ_2 be parts of $\partial\Omega$: $\Gamma_1 \cup \Gamma_2 = \partial\Omega$, $\Gamma_1 \cap \Gamma_2 = \emptyset$. Suppose also that $f(z)$ is specified on Γ_1 , and the problem is to determine $f(z)$ within the interior part of Ω . If $\partial\Omega = \Gamma_1$, the solution is provided by the Cauchy integral,

$$f(z) = \frac{1}{2\pi i} \int_{\partial\Omega} \frac{f(\xi)}{\xi - z} d\xi. \quad (1.47)$$

If $\Gamma_1 \neq \partial\Omega$, then to find the analytic continuation of $f(z)$ is equivalent to the Cauchy problem for the Laplace equation.

Let the value of a harmonic function u and its normal derivative $\partial u/\partial n$ be given on Γ_1 . Denote by $f(z)$ the function

$$f(z) = u(z) + iv(z), \quad z = x + iy, \quad (1.48)$$

where v is the function conjugate to u . It is known that on Γ_1

$$v(z) = \int_{z_0}^z \frac{\partial}{\partial n} u(s) ds + C_1, \quad (1.49)$$

where z_0 is one of the ends of Γ_1 and C_1 a constant. Hence, if $u(z)$, $\partial u(z)/\partial n$ are known on Γ_1 , then the analytic function $f(z)$ may be deemed given on Γ_1 .

²Independent of the specific choice of the norm.

³An analytic function is an infinitely differentiable function such that the Taylor series at any point x_0 in its domain,

$$T(x) = \sum_{n=0}^{\infty} \frac{f^{(n)}(x_0)}{n!} (x - x_0)^n,$$

is convergent for x close enough to x_0 and its value equals $f(x)$.

⁴A function is termed regular if and only if it is analytic and single-valued throughout a region Ω .

From the Cauchy-Riemann conditions it follows that

$$\left. \frac{\partial u}{\partial n} \right|_{\Gamma_1} = \left. \frac{\partial v}{\partial s} \right|_{\Gamma_1}, \quad (1.50)$$

where $\partial v/\partial s$ is the derivative of v along Γ_1 . Taking the derivative of $f(z)$ and $\bar{f}(z)$ along Γ_1 yields⁵

$$\left. \frac{\partial u}{\partial n} \right|_{\Gamma_1} = \left. \frac{1}{2} \frac{\partial}{\partial s} (f - \bar{f}) \right|_{\Gamma_1} \quad (1.51)$$

and we arrive at the Cauchy initial conditions for $u(x, y)$.

Thus, if $\Gamma_1 \neq \partial\Omega$, the problem of analytic continuation is equivalent to the Cauchy problem for the Laplace equation and so is ill-posed.

1.5 How to cure ill-posedness

The property of a non-continuous dependence of the solution on the data strictly applies only to ill-posed problems formulated in infinite dimensional spaces like the ones discussed in the previous section. In practice one has discrete data and one has to solve discrete problems. These, however, are obtained by discretizing problems with very bad mathematical properties. What happens in these cases?

If we consider a linear inverse problem, its discrete version is a linear algebraic system, apparently a rather simple mathematical problem. Many methods exist for solving numerically this problem. However the solution often does not work. A description of the first attempts of data inversions is given by S. Twomey in the preface of his book [Tw77]: 'The crux of the difficulty was that numerical inversions were producing results which were physically unacceptable but were mathematically acceptable (in the sense that *had* they existed they should have given measured values identical or almost identical with what was measured)'. These results were 'rejected as impossible or ridiculous by the recipient of the computer's answer. And yet the computer was often blamed, even though it had done all that had been asked of it'. ...'Were it possible for computers to have ulcers or neuroses there is little doubt that most of those with which early numerical inversion attempts were made would have required both afflictions' [Tw77].

The explanation can be found having in mind the examples discussed in the previous section, where small oscillating data produce large oscillating solutions. In any inverse problem, data are always affected by noise which can be viewed as a small randomly oscillating function. Therefore the solution method amplifies the noise producing a large and wildly oscillating function which completely hides the physical solution corresponding to the noise-free data. This property holds true also for the discrete version of the ill-posed problem. Then one says that the corresponding linear algebraic system is *ill-conditioned*: even if the solution exists

⁵Here, \bar{f} denotes the complex conjugate of f .

and is unique, it may be, and is in general, completely corrupted by a small error on the data.

In conclusion, we have the following situation: we can compute one, and only one, solution of our algebraic system but this solution may be unacceptable for the reasons indicated above; the physically acceptable solution we are looking for is not a solution of the problem but only an approximate solution in the sense that it does reproduce the data not exactly but only within the experimental errors. However, if we look for approximate solutions, we find that they constitute a set which is extremely broad and contains completely different functions, a consequence of the loss of information in the direct problem. Then the question arises: how can we choose the good ones?

We can state now the 'golden rule' for solving inverse problems which are ill-posed: search for approximate solutions satisfying additional constraints coming from the physics of the problem.

The set of the approximate solutions corresponding to the same data function is just the set of objects with images close to the measured one. The set of objects is too broad, as a consequence of the loss of information due to the imaging process. Therefore we need some additional information to compensate this loss. This information, which is also called *a priori* or *prior* information, is additional in the sense that it cannot be derived from the image or from the properties of the mapping A which describes the imaging process but expresses some expected physical properties of the object. Its role is to reduce the set of the objects compatible with the given image or also to discriminate between interesting objects and spurious objects, generated by uncontrolled propagation of the noise affecting the image.

The idea of using prescribed bounds to produce approximate and stable solutions was introduced by C. Pucci in the case of the Cauchy problem for the Laplace equation [Pu55], i.e., the first example of an ill-posed problem discussed by Hadamard. A general version of similar ideas was formulated independently by V.K. Ivanov [Iv62]. His method and the method of D.L. Phillips for Fredholm integral equations of the first kind [Ph62] were the first examples of *regularisation methods* for the solution of ill-posed problems. The theory of these methods was formulated by A.N. Tikhonov one year later [Ti63].

The principle of the regularisation methods is to use the additional information explicitly, at the start, to construct families of approximate solutions, i.e. of objects compatible with the given image. These methods are now one of the most powerful tools for the solution of inverse problems, another one being provided by the so-called Bayesian methods, where the additional information used is of statistical nature.

We will continue the discussion on regularisation methods in the next chapter. First, we will present the generalised solution of inverse problems, describe the regularisation method introduced by Tikhonov and also the truncated singular value decomposition. In the last section, we will give a general definition of a regularisation algorithm and give some properties a regulariser should have so that it gives approximate and stable solutions to inverse problems.

Regularisation of ill-posed problems

2.1 The generalised solution

Given the noisy image $g \in \mathcal{Y}$ and the linear operator A describing the imaging system, we are interested in solving the linear equation

$$Af = g \tag{2.1}$$

for $f \in \mathcal{X}$.

We assume that the operator A has a singular value decomposition so that we can write (see Appendix C)

$$Af = \sum_{j=1}^{\infty} \sigma_j(f, v_j)_{\mathcal{X}} u_j, \tag{2.2}$$

where σ_j are the singular values of A and v_j, u_j are singular functions on \mathcal{X} and \mathcal{Y} respectively.

The problem (2.1) is, in general, ill-posed in the sense that the solution is not unique, does not exist, or else, does not depend continuously on the data.

Uniqueness does not hold when the null-space of the operator A , $\mathcal{N}(A)$, i.e. the set of the invisible objects f such that $Af = 0$, is not trivial.

The procedure most frequently used for restoring uniqueness is the following one. Any element f of the object space \mathcal{X} can be represented by

$$f = \sum_{j=1}^{\infty} (f, v_j)_{\mathcal{X}} v_j + v, \tag{2.3}$$

where v is the projection of f onto $\mathcal{N}(A)$, while the first term is the component of f orthogonal to $\mathcal{N}(A)$. The term v can be called the invisible component of the object f because it does not contribute to the image of f , Af . Since the invisible component cannot be determined from Eq.(2.1), it may be natural to look for a solution of this equation whose invisible component is zero. Such a solution is unique because from Eqs.(2.2) and (2.3), with $v = 0$, we easily deduce that $Af = 0$ implies $f = 0$. If this solution exists, it is denoted by f^+ and called *minimal norm solution*. Indeed, any solution of (2.1) is given by

$$f = f^+ + v, \tag{2.4}$$

where v is an arbitrary element of $\mathcal{N}(A)$. Since v is orthogonal to f^+ , we have

$$\|f\|_{\mathcal{X}}^2 = \|f^+\|_{\mathcal{X}}^2 + \|v\|_{\mathcal{X}}^2 \quad (2.5)$$

and therefore the solution with $v = 0$, i.e., f^+ , is the solution of minimal norm.

As concerns the existence of a solution of (2.1) and, in particular, of f^+ , we first have to distinguish between the following two cases.

- The null space of the adjoint A^* of A , $\mathcal{N}(A^*)$, contains only the zero element. Then the singular functions (vectors) u_j constitute an orthonormal basis in \mathcal{Y} and any noisy image g can be represented by

$$g = \sum_{j=1}^{\infty} (g, u_j)_{\mathcal{Y}} u_j. \quad (2.6)$$

By comparing this representation with the SVD of A , Eq.(2.2), we see that a solution of (2.1) may exist.

- The null space $\mathcal{N}(A^*)$ contains non-zero elements. In such a case the singular functions (vectors) u_j do not constitute an orthonormal basis in \mathcal{Y} and the noisy image g can be represented as follows

$$g = \sum_{j=1}^{\infty} (g, u_j)_{\mathcal{Y}} u_j + u \quad (2.7)$$

where u is the component of g in $\mathcal{N}(A^*)$, i.e. the component of g orthogonal to the range of A . Notice that, if the mathematical model of the imaging system is physically correct, the presence of this term is an effect due to the noise. If $u \neq 0$, by comparing the representation (2.2) of Af with the representation (2.7) of g , we see that there does not exist any object f such that Af coincides with g . Then we can look for objects f such that Af is as close as possible to g , i.e. for objects which minimise the discrepancy functional

$$\|Af - g\|_{\mathcal{Y}} = \text{minimum}. \quad (2.8)$$

Any solution of this variational problem is called a *least-squares solution*.

The concept of least-squares solutions is more general than the concept of solution because a solution of (2.1) is also a least-squares solution. More precisely, the set of the least-squares solutions coincides with the set of the solutions if and only if the minimum of the discrepancy functional (2.8) is zero. This remark shows that, without loss of generality, we can investigate the problem of existence in the case of the least-squares solutions.

Solving problem (2.8) is equivalent to solving its Euler equation, which is given by

$$A^*Af = A^*g. \quad (2.9)$$

From the SVD of the operator A , Eq.(2.2), and of the operator A^*

$$A^*g = \sum_{j=1}^{\infty} \sigma_j(g, u_j)_Y v_j, \quad (2.10)$$

we obtain

$$A^*Af = \sum_{j=1}^{\infty} \sigma_j^2(f, v_j)_X v_j. \quad (2.11)$$

If we insert these representations into Eq.(2.9) and compare the coefficients of v_k , we find that the components of any solution f of (2.9) are given by

$$\sigma_j^2(f, v_j)_X = \sigma_j(g, u_j)_Y, \quad (2.12)$$

and therefore

$$(f, v_j)_X = \frac{1}{\sigma_j}(g, u_j)_Y. \quad (2.13)$$

In such a way the existence of least-squares solutions has been reduced to the existence of elements of the object space \mathcal{X} whose components with respect to the singular functions v_j are given by Eq.(2.13).

According to (2.13) we can introduce the following formal solution

$$f^+ = \sum_{j=1}^{\infty} \frac{1}{\sigma_j}(g, u_j)_Y v_j. \quad (2.14)$$

We say that this solution is formal because it is given by a series expansion so that the solution exists if and only if the series is convergent.

If we consider the convergence in the sense of the norm on \mathcal{X} , then this convergence is assured if and only if the sum of the squares of the coefficients of the eigen-functions v_j is convergent. We obtain the following condition

$$\sum_{j=1}^{\infty} \frac{1}{\sigma_j^2} |(g, u_j)_Y|^2 < \infty \quad (2.15)$$

which is also called the *Picard criterion* for the existence of solutions or least-squares solutions of the linear inverse problem we are considering [Gr93].

It is important to point out that, if the singular values σ_j accumulate to zero then condition (2.15) may not be satisfied by any arbitrary noisy image g . If the condition (2.15) is not satisfied, then *no solution or least-squares solution of the inverse problem exists*.

The functions g satisfying the Picard criterion are images in the range of A , $\mathcal{R}(A)$. For any one of these functions, the series (2.14) defining f^+ is convergent. Then we can conclude that *for any image g satisfying the Picard criterion there*

exists a unique generalised solution f^+ , whose singular function expansion is given by Eq.(2.14).

The generalised solution defines a *generalised inverse operator* A^+ . This operator is not defined everywhere on \mathcal{Y} but only on the set of functions g satisfying the Picard criterion. This set is the domain of the operator A^+ , $\mathcal{D}(A^+)$. Moreover the operator A^+ is not continuous or, in other words, the generalised solution f^+ does not depend continuously on the image g . In order to prove this statement, let us assume that g is an image satisfying the Picard criterion and let us consider a sequence of images given by

$$g_j = g + \sqrt{\sigma_j}u_j. \quad (2.16)$$

If we assume that the singular values tend to zero, which is in general the case, it is obvious that

$$\|g_j - g\|_{\mathcal{Y}} = \sqrt{\sigma_j} \rightarrow 0. \quad (2.17)$$

On the other hand, if we denote by f^+ the generalised solution associated with g , and by f_j^+ the generalised solution associated with g_j , we have

$$f_j^+ = f^+ + \frac{1}{\sqrt{\sigma_j}}v_j \quad (2.18)$$

so that

$$\|f_j^+ - f^+\| = \frac{1}{\sqrt{\sigma_j}} \rightarrow \infty. \quad (2.19)$$

In such a way we have found a sequence of images, converging to g , such that the sequence of the corresponding generalised solutions does not converge to f^+ .

2.2 Tikhonov's regularisation method

The generalised solution of an ill-posed or ill-conditioned problem is not physically meaningful because it may be completely corrupted by the noise propagation from data to solution. For this reason we must look for approximate solutions satisfying additional constraints suggested by the physics of the problem and regularisation is a way for obtaining such solutions.

The starting point is to define a family of *regularised solutions* f_λ , depending on a *regularisation parameter* $\lambda > 0$, as the family of the functions minimising the functionals

$$\Phi_\lambda(f; g) = \|Af - g\|_{\mathcal{Y}}^2 + \lambda \|f\|_{\mathcal{X}}^2 \quad (2.20)$$

where g is the given image. The meaning of the regularisation parameter λ will become clear in Section 2.4, where a general theory of regularisation algorithms will be presented. Let us first discuss how can one find a unique solution to the inverse problem (2.1) which simultaneously minimise the functional (2.20).

The Euler equation associated with the minimisation of this functional is given by

$$(A^*A + \lambda I)f = A^*g. \quad (2.21)$$

An object is a minimum point f_λ of the functional (2.20) if and only if it is a solution of (2.21).

In order to solve this equation, let us represent an arbitrary element f of \mathcal{X} in terms of the singular functions v_j of the operator A and of the elements v (orthogonal to all v_j) of the null space of A , as in Eq.(2.3). If we insert this representation in (2.21) and we take into account Eqs. (2.10) and (2.11), we obtain

$$\sum_{j=1}^{\infty} (\sigma_j^2 + \lambda)(f, v_j)_{\mathcal{X}} v_j + \lambda v = \sum_{j=1}^{\infty} \sigma_j (g, u_j)_{\mathcal{Y}} v_j. \quad (2.22)$$

It follows that there exists a unique solution f_λ of (2.21), which can be obtained from (2.3) with $v = 0$ and with coefficients $(f, v_j)_{\mathcal{X}}$ given by

$$(\sigma_j^2 + \lambda)(f, v_j)_{\mathcal{X}} = \sigma_j (g, u_j)_{\mathcal{Y}}. \quad (2.23)$$

In conclusion we find

$$f_\lambda = \sum_{j=1}^{\infty} \frac{\sigma_j}{\sigma_j^2 + \lambda} (g, u_j)_{\mathcal{Y}} v_j. \quad (2.24)$$

The series at the r.h.s. of this equation does always converge (thanks to the factors σ_j , the coefficients tend to zero more rapidly than the components $(g, u_j)_{\mathcal{Y}}$ of g) and therefore the regularised solution f_λ exists for any noisy image g .

2.3 Truncated SVD

The representation (2.24) of the regularised solution can be recast in the following form

$$f_\lambda = \sum_{j=1}^{\infty} \frac{W_{\lambda,j}}{\sigma_j} (g, u_j)_{\mathcal{Y}} v_j, \quad (2.25)$$

where

$$W_{\lambda,j} = \frac{\sigma_j^2}{\sigma_j^2 + \lambda}. \quad (2.26)$$

This expression shows that the regularised solution f_λ can be obtained by a filtering of the singular value decomposition of the generalised solution: the components of f^+ corresponding to singular values much larger than λ are taken without any significant modification, whereas the components corresponding to singular values much smaller than λ are essentially removed.

One possibility is to replace the smooth filter given in Eq.(2.26) by a sharp one, i.e., to take in the singular function expansion of the generalised solution only the terms corresponding to singular values greater than a certain threshold value. Since the singular values are ordered to form a decreasing sequence, those greater than the threshold value are those corresponding to values of the index less than a certain maximum integer.

Let us denote by J the number of singular values satisfying the condition

$$\sigma_j^2 \geq \lambda, \quad j \leq J, \quad (2.27)$$

then the approximate solution provided by the truncated SVD is as follows

$$F_J = \sum_{j=1}^J \frac{1}{\sigma_j} (g, u_j) y v_j. \quad (2.28)$$

This equation can be obtained from (2.25) by taking $W_{\lambda,j} = 1$ when $\sigma_j^2 \geq \lambda$ and $W_{\lambda,j} = 0$ when $\sigma_j^2 < \lambda$.

2.4 Regularisation algorithms

The methods investigated in the previous sections can be embedded in a more general approach called by Tikhonov the *regularisation method* [Ti63, TA77]. It consists in the introduction of families of continuous approximations to the generalised inverse of the operator A .

A one parameter family of operators $\{R_\lambda\}_{\lambda>0}$ is called a *regularisation algorithm* or a *regulariser* for the solution or general solution of Eq.(1.1), if the following conditions are satisfied [TA77]:

- i) for any $\lambda > 0$, $R_\lambda : \mathcal{Y} \rightarrow \mathcal{X}$ is continuous;
- ii) for any g such that $g \in \mathcal{R}(A)$

$$\lim_{\lambda \searrow 0} \|R_\lambda g - f^+\|_{\mathcal{X}} = 0 \quad (2.29)$$

where f^+ is the generalised solution (or solution when A^{-1} exists) of Eq.(1.1).

When R_λ is linear we have a linear regularisation algorithm; the variable λ is called the regularisation parameter.

Eq.(2.29) can also be written as follows

$$\lim_{\lambda \searrow 0} \|R_\lambda A f^+ - f^+\|_{\mathcal{X}} = 0. \quad (2.30)$$

Therefore the operator $T_\lambda : \mathcal{X} \rightarrow \mathcal{X}$, defined by

$$T_\lambda = R_\lambda A \quad (2.31)$$

is an approximation of the orthogonal projection onto $\mathcal{N}(A)^\perp$ or of the identity operator when $\mathcal{N}(A) = \{0\}$.

Conditions i) and ii) imply that, for any λ and for any exact data $g \in \mathcal{R}(A)$, $R_\lambda g$ is a continuous approximation of the solution or generalised solution of Eq.(1.1). However, the important case is that of noisy data g_ε , with $g_\varepsilon \notin \mathcal{R}(A)$, which are close to exact data $g \in \mathcal{R}(A)$, $\|g_\varepsilon - g\|_Y \leq \varepsilon$, if ε is small enough. In this case, no solution of the equation $Af = g_\varepsilon$ may exist.

If we consider the functions $f_\lambda = R_\lambda g_\varepsilon$, it is easy to see that there must exist an optimum value of λ such that f_λ is as close as possible to f^+ , the generalised solution associated with the exact data g . Assuming that R_λ is linear and that the noisy data g_ε are written in the form $g_\varepsilon = Af + w_\varepsilon$, we get

$$R_\lambda g_\varepsilon - f^+ = (R_\lambda A f^+ - f^+) + R_\lambda w_\varepsilon, \quad (2.32)$$

and therefore

$$\|R_\lambda g_\varepsilon - f^+\|_X \leq \omega(\lambda; f^+) + \varepsilon N(\lambda), \quad (2.33)$$

where

$$N(\lambda) = \|R_\lambda\|, \quad \omega(\lambda; f^+) = \|R_\lambda A f^+ - f^+\|_X \quad \text{and} \quad \varepsilon = \|w_\varepsilon\|_Y. \quad (2.34)$$

The first term of the r.h.s. in Eq.(2.33) represents the approximation error introduced by the choice of a non-zero value of the regularisation parameter; it tends to zero when $\lambda \rightarrow 0$. The second term represents the error on the approximate solution induced by the error on the data; it tends to infinity when $\lambda \rightarrow 0$. Therefore it is necessary to find a compromise between approximation and error magnification. Assume, for simplicity that $N(\lambda)$ and $\omega(\lambda; f^+)$ are monotonous functions of λ (this condition is satisfied by all the regularisation algorithms used in practice) and, more precisely, that $N(\lambda)$ is a decreasing function, with $N(0+) = +\infty$, while $\omega(\lambda; f^+)$ is an increasing function, with $\omega(0+; f^+) = 0$. Under these assumptions, there exists a unique value of λ , $\lambda(\varepsilon)$, which minimises the r.h.s. of Eq.(2.33) and which represents the optimum compromise between approximation and error magnification. Furthermore $\lambda = \lambda(\varepsilon) \rightarrow 0$, when $\varepsilon \rightarrow 0$, and $R_\lambda g_\varepsilon \rightarrow f^+$.

The previous argument implies that a regularisation algorithm can give approximate and stable solutions which converge to the exact solution when the error on the data tends to zero.

The Tikhonov regulariser

The most intensively investigated example of a regularisation algorithm is the so-called Tikhonov regulariser, given by

$$R_\lambda = (A^* A + \lambda I)^{-1} A^*. \quad (2.35)$$

Its remarkable properties derive from the fact that it can be obtained by minimising the functional (2.20) (see Section 2.2). In particular it is easy to show that $R_\lambda g \in$

$\mathcal{N}(A)^\perp$, for any $g \in \mathcal{Y}$ and this implies that $\{R_\lambda\}_{\lambda>0}$ is a regularisation algorithm for f^+ . Using the spectral representation of A^*A , indeed, it is easy to show that

$$\omega(\lambda; f^+) = \|R_\lambda A f^+ - f^+\|_{\mathcal{X}} = \lambda \|(A^*A + \lambda I)^{-1} f^+\|_{\mathcal{X}} \quad (2.36)$$

tends to zero when $\lambda \rightarrow 0$. Furthermore, for any f^+ , $\omega(\lambda; f^+)$ is an increasing function of λ .

It is also easy to find an estimate for $N(\lambda)$, Eq.(2.34),

$$\|R_\lambda g\|_{\mathcal{X}}^2 = (AR_\lambda g, (A^*A + \lambda I)^{-1} g)_Y \leq \frac{1}{\lambda} \|g\|_Y^2 \quad (2.37)$$

since $\|AR_\lambda\| \leq 1$, and therefore

$$N(\lambda) \leq \frac{1}{\sqrt{\lambda}}. \quad (2.38)$$

From this bound and Eq.(2.33) one can derive results concerning possible choices of the function $\lambda(\varepsilon)$.

Spectral windows

The regulariser (2.35) can be written in the following formal way

$$R_\lambda = U_\lambda(A^*A)A^*, \quad (2.39)$$

with the help of the function

$$U_\lambda(\mu) = (\mu + \lambda)^{-1}. \quad (2.40)$$

This remark suggests a way for defining a wide class of regularisation algorithms which can be applied whenever the spectral representation of A^*A is known [Ba65, Gr84].

Consider a family of real-valued, piecewise continuous functions $\{U_\lambda\}_{\lambda>0}$, defined on the interval $[0, \|A\|^2]$ and assume that they satisfy the following conditions:

- i) for each $\lambda > 0$, there exists a constant c_λ such that

$$|U_\lambda(\mu)| \leq c_\lambda; \quad \forall \mu \in [0, \|A\|^2]; \quad (2.41)$$

- ii) for each $\lambda > 0$

$$0 \leq \mu U_\lambda(\mu) \leq 1; \quad \forall \mu \in [0, \|A\|^2]; \quad (2.42)$$

- iii)

$$\lim_{\lambda \searrow 0} \mu U_\lambda(\mu) = 1; \quad \forall \mu \in (0, \|A\|^2]. \quad (2.43)$$

Then the family of operators R_λ , defined by Eq.(2.39) is a regularisation algorithm for f^+ . This result derives from the following remarks. Thanks to condition i), for each $\lambda > 0$, the operator R_λ is bounded. Furthermore the following relation holds:

$$U_\lambda(A^*A)A^* = A^*U_\lambda(AA^*) \quad (2.44)$$

since it is true for polynomials and therefore it is also true for continuous functions. This relation implies that, for any $\lambda > 0$ and any $g \in \mathcal{Y}$

$$f_\lambda = R_\lambda g \in \mathcal{N}(A)^\perp. \quad (2.45)$$

Finally, from the spectral representation of A^*A , from conditions ii) and iii) and the dominated convergence theorem¹, property (2.30) can be derived.

The function $U_\lambda(\mu)$ defined in Eq.(2.40) satisfies the previous conditions. Another important example is given by

$$U_\lambda(\mu) = \begin{cases} 0 & , \quad 0 \leq \mu \leq \lambda \\ \mu^{-1} & , \quad \mu > \lambda \end{cases}. \quad (2.46)$$

For a regularisation algorithm of the type (2.39), the operator T_λ , Eq.(2.31), is

$$T_\lambda = W_\lambda(A^*A), \quad (2.47)$$

where $W_\lambda(\mu) = \mu U_\lambda(\mu)$. The function $W_\lambda(\mu)$ can be called a spectral window. The justification of this name derives from the example (2.46) since in such a case the function $W_\lambda(\mu)$ is zero in a neighbourhood of 0 and is unity elsewhere.

In the case of a compact operator, the regulariser (2.39) can be expressed in terms of the singular value decomposition

$$R_\lambda g = \sum_{k=0}^{\infty} \mu_k^{-1/2} W_\lambda(\mu_k)(g, u_k)v_k. \quad (2.48)$$

In particular, in the case (2.46) we have

$$R_\lambda g = \sum_{\sqrt{\mu_k}} \mu_k^{-1/2} (g, u_k)v_k. \quad (2.49)$$

and this is the well-known method of the truncated singular value decomposition discussed in Section 2.3.

¹The dominated convergence theorem states: Let X be a measurable space and let g, f_1, f_2, \dots be measurable functions such that $\int_X g < \infty$ and $|f_n| \leq g$ for each n . If $f_n \rightarrow f$ almost everywhere, then f is integrable and

$$\lim_{n \rightarrow \infty} \int_X f_n = \int_X f.$$

2.5 Choice of regularisation parameter

The choice of the regularisation parameter is a crucial and difficult problem in the theory of regularisation. This point has been widely discussed in the mathematical literature. No precise recipe has been discovered which could be used for any problem. The existence of a recipe depends a lot on the application and the actual information one has at hand. In what follows we will restrict ourselves to the case of Tikhonov's regularisation algorithm discussed in Section 2.2 and summarise the main methods which are used in practice.

As we know from the discussion of Section 2.4, for any image g there exists an optimum value, λ_{opt} , of the regularisation parameter. For this value of λ , the corresponding regularised solution f_λ has minimal distance from the true object f . The problem is that the determination of this optimal value requires the knowledge of f .

Regularised solution with prescribed energy

If we do not know f but know its norm $E = \|f\|$, also called 'energy', one may try the value $\lambda = \lambda(E)$ such that the corresponding regularised solution has the same energy as the true object, i.e.

$$\|f_\lambda\| = E. \quad (2.50)$$

$\lambda(E)$ is a decreasing function of E . Therefore, if we overestimate the energy of the object, we obtain a value of the regularisation parameter smaller than that corresponding to the exact energy of the object. In such a case the regularised solution will show a higher noise contamination.

Regularised solution with prescribed discrepancy

If we know a precise estimate ε of the energy of the noise, then the estimate is the value $\lambda = \lambda(\varepsilon)$ such that the discrepancy of the corresponding regularised solution is just equal to ε , i.e.

$$\|Af_\lambda - g\| = \varepsilon. \quad (2.51)$$

This method is also known as the discrepancy principle [Mo84]. $\lambda(\varepsilon)$ is an increasing function of ε . Therefore, if we overestimate the energy of the noise, we get a value of the regularisation parameter which is larger than that corresponding to the exact energy of the noise. In such a case the regularised solution will show a smaller noise contamination.

The Miller method

An approach to ill-posed problems proposed by Miller [Mi70] can also be considered as a method for estimating the value of the regularisation parameter. In this approach it is assumed that one knows both a bound on the energy and a bound on the

discrepancy of the unknown object f . Then the set of all objects f satisfying the two conditions

$$\|Af - g\|^2 \leq \varepsilon^2, \quad \|f\|^2 \leq E^2, \quad (2.52)$$

is called the set of admissible approximate solutions. This set corresponds to the intersection of the ball of the objects with squared energy smaller than E^2 and of the ellipsoid of the objects with discrepancy smaller than ε^2 . If this intersection is not empty, then the pair $\{\varepsilon, E\}$ is said to be permissible.

Now, if the pair $\{\varepsilon, E\}$ is permissible, it has been shown by Miller [Mi70] that the regularised solution corresponding to the following value of the regularisation parameter

$$\lambda = \left(\frac{\varepsilon}{E}\right)^2 \quad (2.53)$$

satisfies the condition (2.52) except for a factor of $\sqrt{2}$ and therefore it is essentially an admissible approximate solution.

Generalised cross-validation

The methods considered previously require the knowledge of ε or of E or of both. In many cases one does not have a sufficiently accurate estimate of these quantities and therefore it is important to have methods which do not require this kind of information. One such method is that of cross-validation [Wa77] which can only be used in problems with discrete data. It is based on the idea of letting the data themselves choose the value of the regularisation parameter. In other words one requires that a good value of the regularisation parameter should predict missing data values.

The mathematical formulation of this method is more complicated and will not be presented here. For more details one can look in [BB98].

L-curve method

This graphically motivated method, introduced by Hansen [Ha92], is another method which does not require information about the energy of the noise or of the true object. The starting point is the plot of $E(f_\lambda)$ versus $\varepsilon(f_\lambda; g)$, introduced in connection with Miller's method. This curve has, in many cases, a rather characteristic L-shaped behaviour in a log-log plot.

A qualitative explanation of this behaviour is the following. We recall that $E(f_\lambda)$ is large for small λ and small for large λ while $\varepsilon(f_\lambda; g)$ has the opposite behaviour. Therefore $E(f_\lambda)$ is large when $\varepsilon(f_\lambda; g)$ is small, and conversely. This is the trade-off between noise-propagation error and approximation error. Now the vertical part of the L-curve corresponds to values of the regularisation parameter such that f_λ is dominated by the noise propagation error. As a consequence $E(f_\lambda)$ is very sensitive to variations of λ while $\varepsilon(f_\lambda; g)$ is not. Analogously the horizontal part of the L-curve corresponds to values of the regularisation parameter such that f_λ is dominated by

the approximation error. As a consequence $\varepsilon(f_\lambda; g)$ is very sensitive to variations of λ while $E(f_\lambda)$ is not.

Now the L-curve method consists of taking as an estimate of the regularisation parameter the value of λ corresponding to the corner of the L-curve. In fact this point should correspond to the compromise between approximation error and noise-propagation error. From the computational point of view a convenient definition of the L-curve corner is the point with maximum curvature.

The L-curve method, even if it can be useful in some cases, does not work in all cases and has some theoretical and practical inconveniences. It has been shown [EG94, Vo96] that, in certain cases, it does not provide a regularised solution converging to the exact one when the noise tends to zero. Moreover, examples can be found where the L-curve does not even have an L-shape so that the method cannot be used.

The interactive method

The speed and versatility of modern digital computers allows us to restore images interactively: the user controls the restorations obtained by means of several values of the regularisation parameter and, by tuning λ , he selects the best restoration on the base of his intuition or of the attainment of some specific purpose.

QCD condensates from τ -decay data

The theory of τ -decays

The τ is the only lepton heavy enough ($m_\tau = 1.777$ GeV) to decay not only into other leptons, but into final states involving hadrons as well. These decays offer an ideal laboratory for the study of strong interactions, including the transition from the perturbative to the non-perturbative regime of QCD in the simplest possible reaction. This might explain the tremendous efforts ongoing in both theoretical and experimental studies of τ physics (for a review see [St00]).

The *leptonic* decays are:

$$\begin{array}{l} \tau \rightarrow \nu_\tau + W \\ \quad \searrow \\ \quad l^- + \bar{\nu}_l \end{array} \quad l = \mu \text{ or } e. \quad (3.1)$$

We will write formulas for $\tau = \tau^-$; the formulas for τ^+ are obtained with obvious changes. Besides the decays (3.1), we have *hadronic* decays. At the parton level these are given by the processes

$$\begin{array}{l} \tau \rightarrow \nu_\tau + W \\ \quad \searrow \\ \quad q_i + \bar{q}_j \end{array} \quad (3.2)$$

where the flavour indices i, j stand for the light quarks (u, d, s). The Feynman diagram for Eqs.(3.1) and (3.2) is shown in Fig.3.1.

The permitted hadronic decays may be split into decays that involve only non-strange particles

$$\begin{array}{l} \tau \rightarrow \nu_\tau + W \\ \quad \searrow \\ \quad d + \bar{u}, \end{array} \quad (3.3)$$

or decays involving strange particles

$$\begin{array}{l} \tau \rightarrow \nu_\tau + W \\ \quad \searrow \\ \quad s + \bar{u}. \end{array} \quad (3.4)$$

Although the theory will be presented in general, i.e., for both types of decay, we are especially interested in the non-strange ones.

Figure 3.1: Leptonic and hadronic decays of τ at zeroth order in α_s .

3.1 Hadronic τ -decays

The decay of the τ lepton into hadrons (see Fig.3.1) was calculated by Paul Tsai [Ts71], even before the discovery of the τ . Ignoring the propagator of the W^\pm boson, the matrix element is given by the product of the leptonic and the hadronic current:

$$i\mathcal{M} = \frac{G_F}{\sqrt{2}} \langle \tau | J_{\text{lep}}^\mu J_{\text{had},\mu} | \text{had}, \nu_\tau \rangle, \quad (3.5)$$

where G_F is the Fermi constant. The leptonic current is the standard left-handed one, $J_{\text{lep}}^\mu = \bar{\tau} \gamma^\mu (1 - \gamma_5) \nu_\tau$, while the hadronic current can be any of the vector $J_{\text{had}}^\mu = \sum_{i,j} V_{ij} \bar{q}_i \gamma^\mu q_j$, axial-vector current $J_{\text{had}}^\mu = \sum_{i,j} V_{ij} \bar{q}_i \gamma^\mu \gamma_5 q_j$ or combinations of them. By convention, we have included in the definition of the hadronic current part of its coupling to the W boson, the CKM mixing matrix element V_{ij} . Other factors were explicitly taken into account when writing out the matrix element (3.5).

With this matrix element, one can calculate the decay width $\Gamma(\tau \rightarrow \nu_\tau + \text{had})$ as [BNP92, Na88a]

$$d\Gamma(\tau \rightarrow \nu_\tau + \text{had}) = \frac{1}{2m_\tau} (2\pi)^4 \delta^{(4)}(p_{\text{had}} - q) \frac{G_F^2}{2} L^{\mu\nu} \times \sum_{\text{had}} i \int d^4x e^{iqx} \langle 0 | J_{\text{had},\mu}(x) | \text{had} \rangle \langle \text{had} | J_{\text{had},\nu}^\dagger(0) | 0 \rangle d\phi_{\text{had}} d\phi_{\nu_\tau}, \quad (3.6)$$

where $d\phi$ denotes the invariant phase space elements of the hadrons and the neutrino, and $L^{\mu\nu}$ is the leptonic tensor. The total 4-momentum of the hadronic system is written as q ($q^2 \equiv s$). Now the optical theorem (Fig.3.2) can be used to write the matrix element for the production of hadrons in terms of the imaginary part of the forward scattering amplitude:

$$d\Gamma(\tau \rightarrow \nu_\tau + \text{had}) = \frac{1}{2m_\tau} \frac{G_F^2}{\sqrt{2}} L^{\mu\nu} 2 \text{Im} i \int d^4x e^{iqx} \langle 0 | T J_{\text{had},\mu}(x) J_{\text{had},\nu}^\dagger(0) | 0 \rangle d\phi_{\nu_\tau}. \quad (3.7)$$

Figure 3.2: The optical theorem relates the production of hadrons from τ decays (left diagram) to the imaginary part of the forward scattering amplitude of the diagram on the right.

This is quite an important step. While (3.6) requires the calculation of matrix elements of exclusive final states (and their summation), Eq.(3.7) contains no explicit reference to hadronic final states. The first one cannot be handled by perturbative QCD, but the second one can.

We may split the hadron tensor into a transverse and a longitudinal part, writing

$$\begin{aligned} \Pi_{\mu\nu}(q) &= i \int d^4x e^{iqx} \langle 0 | T J_{\text{had},\mu}(x) J_{\text{had},\nu}^\dagger(0) | 0 \rangle \\ &= (q_\mu q_\nu - g_{\mu\nu} q^2) \Pi^{(1)}(q^2) + q_\mu q_\nu \Pi^{(0)}(q^2). \end{aligned} \quad (3.8)$$

The two functions $\Pi^{(J)}$ introduced here are called the two-point correlators of the quark currents (see Section 3.4). They describe the creation of hadronic states with total angular momentum J from the vacuum. The integration over the phase space of the neutrino can now be performed. The result is

$$\begin{aligned} \Gamma(\tau \rightarrow \nu_\tau + \text{had}) &= \\ &= \frac{G_F^2 m_\tau^5}{16\pi^2} \int_0^{m_\tau^2} \frac{ds}{m_\tau^2} \left(1 - \frac{s}{m_\tau^2}\right)^2 \left\{ \left(1 + 2\frac{s}{m_\tau^2}\right) \text{Im}\Pi^{(1)}(s) + \text{Im}\Pi^{(0)}(s) \right\}. \end{aligned} \quad (3.9)$$

3.2 Leptonic τ -decays

The leptonic decay width can be calculated in a straightforward way from the Feynman diagram of Fig.3.1 as well. It is sufficient to treat the process as an effective four-fermion interaction and add the effect from the W^\pm propagator as a correction later. The result is

$$\Gamma(\tau \rightarrow \nu_\tau \bar{\nu}_l l) = \frac{G_F^2 m_\tau^5}{192\pi^3} (1 + \Delta_l). \quad (3.10)$$

The quantity Δ_l collects a number of corrections shown in Table 3.1. The table also shows corrections which are not present in the Standard Model but will modify the decay width if new physics is present. Indeed, a massive neutrino would change the phase space of the decays and consequently the decay width. The direct limits

Standard Model corrections	
phase space correction due to the finite mass m_l of the charged daughter lepton [BS88]	$-8 \left(\frac{m_l}{m_\tau} \right)^2$
QED radiative corrections [Be58, KS59, Kä68, MS88, RS71, Si78]	$\frac{\alpha(m_\tau^2)}{2\pi} \left(\frac{25}{4} - \pi^2 \right)$
correction due to the W^\pm propagator [LY57]	$\frac{3}{5} \left(\frac{m_\tau}{m_{W^\pm}} \right)^2$
Corrections due to new physics	
neutrino mass [BS88]	$-8 \left(\frac{m_{\nu_\tau}}{m_\tau} \right)^2$
scalar current [St94]	$4\eta \frac{m_l}{m_\tau}$
mixing with a 4th generation ν [ST97]	$-\sin^2 \theta$
magnetic dipole moment [Ri97]	$\frac{\kappa}{2} + \frac{\kappa^2}{10}$
electric dipole moment [Ri97]	$\frac{\tilde{\kappa}^2}{10}$

Table 3.1: Corrections (contributions to Δ_l) to the leptonic width of the τ lepton.

on the mass of ν_e and ν_μ are so strict that these cannot have a measurable impact, but the ν_τ could. Also, mixing with a yet undiscovered, heavy, fourth-generation neutrino would reduce the decay width. The authors of [DST98, ST97] derived from universality limits for:

$$m_{\nu_\tau} < 38\text{MeV}, \quad \sin^2 \theta < 0.008 \quad (3.11)$$

at the 95% CL.

A charged Higgs boson would introduce a scalar coupling and therefore a non-vanishing Michel parameter η , which in turn modifies the decay width. A limit on these bosons has been found [St94, St98]:

$$m_{H^\pm} > 2.3 \tan \beta, \quad (3.12)$$

at the 95% CL. An estimate of the Michel parameter is [St94]:

$$\eta = 0.01 \pm 0.05. \quad (3.13)$$

An anomalous magnetic moment or an electric dipole moment of the charged weak current, usually parametrised with the help of parameters κ and $\tilde{\kappa}$ [St00],

would modify the decay width. The correction is given in Table 3.1. Limits have been derived in [DST98]. They are (95% CL)

$$-0.015 < \kappa < 0.017, \quad |\tilde{\kappa}| < 0.31. \quad (3.14)$$

Nevertheless, the corrections are small ($< 4\%$) and can be safely neglected.

3.3 The hadronic branching ratio R_τ

R_τ is defined as the ratio of the total hadronic decay width $\Gamma(\tau \rightarrow \nu_\tau + \text{had})$ to the leptonic one:

$$R_\tau \equiv \frac{\Gamma(\tau \rightarrow \nu_\tau + \text{had})}{\Gamma(\tau \rightarrow \nu_\tau \bar{\nu}_e e)}. \quad (3.15)$$

With the earlier computed decay widths of Eqs. (3.9) and (3.10), the hadronic branching ratio becomes:

$$R_\tau = 12\pi \int_0^{m_\tau^2} \frac{ds}{m_\tau^2} \left(1 - \frac{2s}{m_\tau^2}\right)^2 \left[\left(1 + 2\frac{s}{m_\tau^2}\right) \text{Im}\Pi^{(1)}(s) + \text{Im}\Pi^{(0)}(s) \right]. \quad (3.16)$$

3.4 Operator Product Expansion (OPE)

As a consequence of asymptotic freedom the theoretical results obtained from QCD can be compared with the experimental situation for so-called hard, i.e. high energy, processes: at short distances the effective coupling constant $\bar{\alpha}_s$ becomes small and the interaction can be treated perturbatively. On the other hand, any complete theory of the strong interaction must include large-distance dynamics as well. In particular quarks interact strongly when forming hadronic bound states.

A great deal of effort has been made towards the construction of new tools for reliable computations in the non-perturbative region of QCD. Most of the efforts to obtain quantitative results can be divided into two categories [Pa80]: numerical computations and analytic calculations. Numerical computations are usually time consuming and require powerful computers (sometimes specially designed). They are mainly based on lattice gauge theories [Ko79, Wi74] and are producing promising results [HMPR81].

There are several approaches using analytical calculations. For several years much effort has been devoted to the search for classical solutions of non-abelian field theories [Ch78] with the hope that a semiclassical approach may shed some light on the underlying quantum world and that classical configurations of fields that make the action stationary play an important role in the problem of confinement.

An interesting new approach based on the operator product expansion was opened in 1979 [SVZ79a, SVZ79b, SVZ79c]. This approach is less fundamental in the sense that it does not try to solve the problem of confinement but assumes that confinement exists. In practice the effects of confinement can be described through the

use of a few parameters, the so called condensates, and this allows one to investigate many hadronic properties.

As stated above, one of the ingredients of this approach is the operator product expansion [Wi69]. Wilson proposed a short distance operator product expansion of the following form

$$A(x)B(0) \underset{x^\mu \rightarrow 0}{\sim} \sum_n C_n(x) \mathcal{O}_n(0), \quad (3.17)$$

where A and B are local operators. The $C_n(x)$ are \mathbb{C} -number functions which can have singularities on the light cone of the form $[x^2 - i\epsilon x^0]^{-p}$, p being any real number. They can also involve logarithms of x^2 . In general, the complete expansion involves an infinite number of non-singular operators \mathcal{O}_n but to any finite order in x only a finite number of these operators contributes. The expansion is valid in the weak sense: one must sandwich the product $A(x)B(0)$ between fixed initial and final states. Similar expansions exist for time-ordered products or commutators. The OPE can be verified explicitly for the free scalar and spinor field theories and for renormalised interacting fields to any finite order in perturbation theory. In every case they are valid for any elementary or composite local fields.

The nature of the singularities of the functions $C_n(x)$ is determined, in general, by exact and broken symmetries of the theory. The most crucial of these symmetries is broken scale invariance. The free scalar and spinor field theories with zero mass are exactly scale invariant. Mass terms and renormalizable interactions treated in perturbation theory break the symmetry but some remainder of scale invariance still governs the behaviour of the singular functions [Wi69]. Exact scale invariance means that the field theory is invariant under a one-parameter group of transformations $U(\lambda)$. A local operator $\mathcal{O}_n(x)$ transforms as

$$U^\dagger(\lambda) \mathcal{O}_n(x) U(\lambda) = \lambda^{d(\mathcal{O}_n)} \mathcal{O}_n(\lambda x). \quad (3.18)$$

In free field theories the constant $d(\mathcal{O}_n)$ is the canonical dimension of the field, i.e. $[\mathcal{O}_n(x)] = M^{d(\mathcal{O}_n)}$, which can be determined for example from the commutation relations.

In an exactly scale-invariant theory the behaviour of the functions $C_n(x)$ is determined, except for some constants, by scale invariance. Performing a scale transformation in

$$A(x)B(y) \underset{x^\mu \rightarrow y^\mu}{\sim} \sum_n C_n(x - y) \mathcal{O}_n(y), \quad (3.19)$$

we obtain

$$\lambda^{d(A)+d(B)} A(\lambda x) B(\lambda y) \underset{x^\mu \rightarrow y^\mu}{\sim} \sum_n C_n(\lambda x - \lambda y) \lambda^{d(\mathcal{O}_n)} \mathcal{O}_n(y). \quad (3.20)$$

If the fields $\mathcal{O}_n(x)$ are linearly independent, which can always be arranged, one must have

$$C_n(\lambda x - \lambda y) = \lambda^{d(\mathcal{O}_n) - d(A) - d(B)} C_n(x - y). \quad (3.21)$$

This equation tells us that $C_n(x - y)$ must be a homogeneous function of order $d(\mathcal{O}_n) - d(A) - d(B)$ in $(x - y)$. This property as well as the behaviour under Lorentz transformations determines $C_n(x - y)$ completely, up to a finite number of constants [Sc71]. When we turn on the interactions [Wi69], it is still true that the \mathbb{C} -number functions $C_n(x)$ have a scaling behaviour, as $x^\mu \rightarrow 0$, which can be summarised with the rules

$$C_n(x) \underset{x^\mu \rightarrow y^\mu}{\sim} x^{-\lambda_n}, \quad \lambda_n \equiv d(A) + d(B) - d(\mathcal{O}_n), \quad (3.22)$$

except that the operator dimensions are no longer given by naive counting of the mass dimensions of the operators: they become *anomalous* in general [Co71]. There are, nevertheless, some operators which retain their naive dimensions: these include the identity I , and the operators generating symmetries of the theory, such as currents $J^\mu(x)$ or the field operator $G_a^{\mu\nu}$.

The operators \mathcal{O}_n are conveniently classified according to their spin and dimension $d(\mathcal{O}_n)$. In particular, if A and B are scalars, and gauge invariant, only scalar, gauge-invariant operators have to be considered.

Interesting for us is the case of QCD where the two operators A, B are constructed from quark and gluon fields. In this case, the lowest dimension scalar, gauge-invariant operators are:

- dimension 0: I (the unit operator)
- dimension 4: $: m_i \bar{q}_\alpha^i q_\alpha^i :$ (no summation in flavours)
 $: G_a^{\mu\nu}(x) G_{\mu\nu}^a(x) :$
- dimension 6: $: \bar{q}_\alpha(x) \Gamma q_\alpha(x) \bar{q}_\beta(x) \Gamma q_\beta(x) :$
 $: \bar{q}_\alpha(x) \Gamma (\lambda^a)_{\alpha\beta} q_\beta(x) \bar{q}_\gamma(x) \Gamma (\lambda^a)_{\gamma\sigma} q_\sigma(x) :$
 $: m_i \bar{q}^i(x) \lambda^a \sigma_{\mu\nu} q^i(x) G_a^{\mu\nu}(x) :$
 $: f_{abc} G^{\mu\nu,a}(x) G_{\nu\rho}^b(x) G_{\mu\rho}^c(x) :$

where the first two operators of dimension 6 have been given only for one flavour. Γ denotes any combination of Dirac matrices and therefore for a given flavour there are 16 such quantities ($I, \gamma^\mu, \sigma^{\mu\nu}, \gamma^\mu \gamma_5, \gamma_5$) that render a scalar operator. Any other gauge invariant scalar operator of the same dimension can be reduced to these with the help of the equations of motion. Notice that the use of the equations of motion is legitimate because expectation values in physical states will be taken and the equations of motion are satisfied if restricted to the space of physical states.

Within standard perturbation theory only the unit operator would have a non-zero vacuum expectation value, but non-perturbative effects induce non-vanishing vacuum expectation values for operators of higher dimensions as well. These are the so-called *condensates*. Therefore non-perturbative effects of QCD introduce power corrections of the type $1/[q^2]^N$, $N \geq 1$, to the perturbative calculation.

3.5 Hadronic vacuum polarisation tensor

The hadronic vacuum polarisation tensor is defined as (cf. Eq.(3.8)):

$$\Pi_{ij}^{\mu\nu} = i \int d^4x e^{iqx} \langle 0 | T J_{ij}^\mu(x) J_{ij}^\nu(0)^\dagger | 0 \rangle, \quad (3.23)$$

where $J_{ij}^\mu = \bar{q}_i \gamma^\mu (\gamma_5) q_j$ are the vector (axial-vector) hadronic currents describing electroweak interactions, i, j are flavour indices and T stands for time ordering. Performing a Lorentz decomposition, we can split $\Pi_{ij}^{\mu\nu}$ into a transverse and a longitudinal part (cf. Eq.(3.8)):

$$\Pi_{ij}^{\mu\nu}(q) = (q_\mu q_\nu - g_{\mu\nu} q^2) \Pi_{ij}^{(1)}(q^2) + q_\mu q_\nu \Pi_{ij}^{(0)}(q^2), \quad (3.24)$$

where the indices $J = 0, 1$ in $\Pi_{ij}^{(J)}$ refer to the total spin carried by the correlator. The conservation of the vector current implies $\Pi_{ij,V}^{(0)} = 0$. The imaginary parts of Π_{ij} give the spectral functions:

$$\begin{aligned} \text{Im} \Pi_{ij,V}^{(1)}(s) &= \frac{1}{2\pi} v_1^{ij}(s), \\ \text{Im} \Pi_{ij,A}^{(1)}(s) &= \frac{1}{2\pi} a_1^{ij}(s), \\ \text{Im} \Pi_{ij,A}^{(0)}(s) &= \frac{1}{2\pi} a_0^{ij}(s), \end{aligned} \quad (3.25)$$

which provide the basis for comparing short distance theory with hadronic data.

Defined as a time ordered product of local operators, the hadronic polarisation tensor can be rewritten using the OPE (see Section 3.4):

$$\Pi_{ij}^{(J),V/A}(s) = \sum_{d \geq 0} \frac{\mathcal{O}_d^{(J),V/A}}{(-s)^{d/2}}, \quad (3.26)$$

where $\mathcal{O}_d \equiv \mathcal{C}_d \langle \mathcal{O}_d \rangle$ is the short hand notation for the QCD non-perturbative condensate $\langle \mathcal{O}_d \rangle$ of dimension d and its associated perturbative Wilson coefficient \mathcal{C}_d ; $s \equiv q^2$ is the momentum transfer. $\langle \mathcal{O}_d \rangle$ are vacuum expectation values of gauge invariant scalar operators constructed out of quark and gluon fields and called condensates. A more detailed discussion of them is found in Chapter 5.

The dimension $d = 0$ contribution to (3.26) is entirely given by perturbation theory (recall that $\langle \mathcal{O}_0 \rangle = I$, Section 3.4). For that reason it is useful to separate the two contributions in (3.26)

$$\Pi_{ij}^{(J),V/A}(s) = \Pi_{ij,PT}^{(J),V/A}(s) + \Pi_{ij,OPE}^{(J),V/A}(s). \quad (3.27)$$

A convenient way to calculate the perturbative part is to use the Adler function which is perturbatively constructed as an expansion in the coupling constant:

$$D(s) \equiv -s \frac{d}{ds} \Pi(s) = \frac{1}{4\pi^2} \sum_{n \geq 0} K_n a^n, \quad a \equiv \frac{\alpha_s}{\pi} \left(\Pi(s) \equiv \Pi_{ij,PT}^{(J),V/A}(s) \right). \quad (3.28)$$

The renormalization group equation for $a(s)$, $s = -Q^2$, reads:

$$\begin{aligned} \frac{da}{d \ln Q^2} &= -\beta(a) = -\sum_{n \geq 0} \beta_n a^{n+2} \\ \Rightarrow \ln \frac{Q^2}{\mu^2} &= -\int_{a(\mu^2)}^{a(Q^2)} \frac{da}{\beta(a)}. \end{aligned} \quad (3.29)$$

In the $\overline{\text{MS}}$ scheme for 3 flavours $\beta_0 = 9/4$, $\beta_1 = 4$, $\beta_2 = 10.06$, $\beta_3 = 47.23$ [La93, RVL97, TVZ80]. This allows one to get the perturbative contribution to the polarisation operator explicitly at any order of perturbation theory:

$$\Pi(s) - \Pi(\mu^2) = \frac{1}{4\pi^2} \int_{a(\mu^2)}^{a(Q^2)} D(a) \frac{da}{\beta(a)}. \quad (3.30)$$

The second term in Eq.(3.27) is given by the OPE expansion, but now starting with dimension $d = 2$.

Figure 3.3: Region of validity of the operator product expansion.

The Adler function constructed in this way has an unphysical cut from $s = -Q_0^2$ to $s = 0$. It is an obvious indication of the fact that QCD is inapplicable at low $|s|$. Also, the expression (3.26) is not valid for all values of s , the series not converging for small $|s|$, where the effective degrees of freedom are hadrons rather than quarks. The exact polarisation tensor is known to be an analytical function of s with a cut along the positive real semi-axis, while the OPE series with a finite number of operators has a very singular behaviour at $s = 0$ and a possible cut, on the positive real semi-axis, starting at some $s_0 > 0$. Based upon these arguments one may draw schematically in Fig.3.3 the region of validity of the series (3.26).

3.6 Dispersion relations

A dispersion relation connects the real part of an analytic function to its absorptive (imaginary) part. The name is due to physicists and it is not found in the mathematical literature. Similar problems have been studied by the mathematicians under names such as Hilbert transforms, the Riemann-Hilbert problem, the Wiener-Hopf method and Carleman's method. The physicist's name arises from the original applications of the technique by Kramers and Kronig to the study of the index of refraction describing the dispersion of light waves. More recently, further refinements of the method have been employed extensively in elementary particle theory as an alternative to perturbative QCD.

We will first briefly state the mathematical basis without any indication to physics. Later on, an application to the two point functions of the previous section will be considered.

Let us consider a complex-valued function, $F(s)$ (which will later be identified with $\Pi(s)$), of complex argument, s , and assume that:

- $F(s)$ is real for real $s < s_0$;
- $F(s)$ has a branch cut for real $s > s_0$;
- $F(s)$ is analytic for complex s (except along the cut).

Figure 3.4: Contour \mathcal{C} of Eq.(3.32) in the complex s -plane.

We fix the sign of the absorptive (imaginary) part of F along the branch cut by

$$F(s + i\varepsilon) = \text{Re}F(s) + i\text{Im}F(s), \quad (3.31)$$

where $\varepsilon > 0$ is infinitesimal. Since F is analytic at each point q^2 within the contour

\mathcal{C} (Fig.3.4), we may apply Cauchy's theorem to find

$$\begin{aligned}
F(q^2) &= \frac{1}{2\pi i} \oint_{\mathcal{C}} ds \frac{F(s)}{s - q^2} \\
&= \frac{1}{2\pi i} \left(\int_{s_0}^{\Lambda^2} ds \frac{F(s + i\varepsilon) - F(s - i\varepsilon)}{s - q^2} + \oint_{|s|=\Lambda^2} ds \frac{F(s)}{s - q^2} \right) \\
&= \frac{1}{\pi} \int_{s_0}^{\Lambda^2} ds \frac{\text{Im}F(s)}{s - q^2 - i\varepsilon} + \frac{1}{2\pi i} \oint_{|s|=\Lambda^2} ds \frac{F(s)}{s - q^2},
\end{aligned} \tag{3.32}$$

where, in the last step, we have used Schwartz' reflection principle:

$$F(s + i\varepsilon) - F(s - i\varepsilon) = 2i\text{Im}F(s). \tag{3.33}$$

Suppose that we only know $\text{Im}F$ along the branch cut and wish to evaluate F at some point q^2 . Then, Eq.(3.32) is not useful since F also appears on the r.h.s. under the integral along the circle. However, if

$$\lim_{\Lambda^2 \rightarrow \infty} \oint_{|s|=\Lambda^2} ds \frac{F(s)}{s - q^2} = 0, \tag{3.34}$$

then we obtain the unsubtracted dispersion relation

$$F(q^2) = \frac{1}{\pi} \int_{s_0}^{\Lambda^2} ds \frac{\text{Im}F(s)}{s - q^2 - i\varepsilon}. \tag{3.35}$$

This means that F can be reconstructed at any point q^2 from the knowledge of its absorptive part along the cut. In particular, the dispersive (real) part of F may be evaluated from

$$\text{Re}F(q^2) = \frac{1}{\pi} \mathbb{P} \int_{s_0}^{\Lambda^2} ds \frac{\text{Im}F(s)}{s - q^2 - i\varepsilon}. \tag{3.36}$$

In general, Eq.(3.34) is not satisfied, but instead one has

$$\lim_{\Lambda^2 \rightarrow \infty} \oint_{|s|=\Lambda^2} ds \frac{F(s)}{s - q^2} = a + bq^2 + \dots, \tag{3.37}$$

and thus

$$\text{Re}F(q^2) = \frac{1}{\pi} \mathbb{P} \int_{s_0}^{\Lambda^2} ds \frac{\text{Im}F(s)}{s - q^2 - i\varepsilon} + a + bq^2 + \dots. \tag{3.38}$$

The coefficients of the polynomial in (3.38), a, b, \dots , depend on the properties of F .

For the two point functions of the previous section, $\Pi(s)$, one will then have the dispersion relation

$$\text{Re}\Pi(q^2) = \frac{1}{\pi} \mathbb{P} \int_{s_0}^{\infty} ds \frac{1}{s - q^2} \text{Im}\Pi(s) + a + bq^2 + \dots. \tag{3.39}$$

Here, the physical meaning of the coefficients a, b, \dots , depends of course on the choice of the local operator $J(x)$ in the two-point function. In some cases the coefficients in question are fixed by low-energy theorems; e.g. if $\Pi(0)$ is known, we can trade the constant a in (3.39) for $\Pi(0)$:

$$\operatorname{Re}\Pi(q^2) = \operatorname{Re}\Pi(0) + \frac{1}{\pi} \mathbb{P} \int_{s_0}^{\infty} ds \frac{q^2}{s} \frac{\operatorname{Im}\Pi(s)}{s - q^2} + bq^2 + \dots . \quad (3.40)$$

In general, it is always possible to get rid of the polynomial terms by taking an appropriate number of derivatives with respect to q^2 .

Hadronic spectral functions

The τ lepton was discovered in 1974 from a handful of $e - \mu$ events. In the 30 years following the discovery, τ physics has matured into a field of high precision, testing many aspects of our current understanding of particle physics:

- The coupling of the τ lepton to the charged weak current has been tested at the level of a few parts per thousand. Its couplings to the weak neutral current have been measured with similar precision.
- Substantial contributions to precision tests of the electroweak theory at LEP and SLC have been derived from τ production data.
- The coupling to the photon has been investigated. No anomalies have been found so far.
- More than 100 different, mainly hadronic, branching ratios have been measured, allowing tests of QCD and many model predictions.
- The spectral functions have been determined. They allow one to study perturbative QCD at low energy scales and provide one of the most precise measurements of the strong coupling constant α_s .
- The structure of the charged current in τ decays has been examined for deviations from $V - A$. These investigations are sensitive to many kinds of new physics.
- CP violation in the production or decay of the τ lepton is a very interesting question which has been analysed in a search for a deeper understanding of the origin of CP violation.
- In the light of neutrino oscillations, lepton-flavour-violating τ decays are expected to occur at some level.
- The searches for a finite mass of the τ neutrino are approaching 10 MeV, thereby closing an interesting astrophysical window.

We are especially interested in the hadronic spectral functions. They are the basic ingredients to the theoretical description of τ decays, since they represent the probability to produce a given hadronic system from the vacuum, as a function of its invariant mass squared s . The spectral functions are dominated by known

resonances, but tend to approach the quark-level asymptotic regime at m_τ^2 . They have been determined for individual hadronic modes, however they are summed and separated into their inclusive vector and axial-vector components for the non-strange part. The Cabbibo-suppressed strange part cannot be separated at present, due to the lack of necessary experimental information.

The non-strange τ vector spectral functions can be compared to the corresponding quantities obtained in e^+e^- annihilation by the virtue of isospin symmetry. The precision reached in the experimental data makes it necessary to correct for isospin-symmetry breaking. Beyond overall agreement, the detailed comparison unveils discrepancies with results from e^+e^- data annihilation. The vector spectral functions are necessary ingredients to compute vacuum polarisation integrals, required for the evaluation of the running coupling constant α_s or the anomalous magnetic moment of the muon a_μ . The disagreement leads to different results when using τ or e^+e^- spectral functions. While the e^+e^- -based theoretical value of a_μ disagrees with the measured one by 3.4σ [MRR07], possibly indicating contributions from physics beyond the SM, the τ -based calculation is consistent with experiment. Although the use of e^+e^- data is *a priori* more direct, the present situation must evolve, requiring more experimental and theoretical cross-checks.

The observation that hadronic spectral functions derived from τ -decay data can provide precision information on perturbative QCD is surprising, considering the moderate energy scale involved in these decays. Hence it is useful to recall briefly the reasons behind this success:

- The total hadronic decay rate normalised to the leptonic width, R_τ , is obtained by integrating the total spectral function weighted by a known kinematic factor originating from the $V - A$ leptonic tensor. This integral can be transformed to a complex contour integral over a circle at $|s| = m_\tau^2$, hence involving only large complex s values where perturbative QCD can presumably be applied;
- One factor in the weight function, $(1 - s/m_\tau^2)^2$, cuts off the integrand in the vicinity of the real axis where poles of the current correlator are located;
- The invariant-mass spectra in the hadronic τ decay, dominated by resonances, are thus related to the quark-level contributions expected at large mass. This global quark-hadron duality is expected to work best in more inclusive situations. In the case of hadronic τ decays, this condition seems to be well met, with few resonance contributions in each of the equally important vector and axial-vector components;
- The perturbative expansion of the spectral function is known to the third order in α_s [CKT79, CG80, DS79, GKL91, SS91]; estimates of the fourth order coefficient are also available [BCK03, KS95];
- The perturbative and non-perturbative contributions can be treated systematically using the OPE, giving corrections with inverse powers d of m_τ ;

- The *a priori* dominant non-perturbative term from the gluon condensate ($d = 4$) is suppressed by the second factor of the weight function, $(1 + 2s/m_\tau^2)^{-1}$. This accidental fact renders hadronic τ decays particularly favourable since non-perturbative effects are expected to be small;
- The next $d = 6$ term is subject to a partial cancellation between the vector V and axial-vector A contributions, due to the $(1 - \gamma_5)$ factor of the weak current.

4.1 Overview of experiments

Since its discovery, the τ lepton has been studied with ever-increasing precision at every new e^+e^- collider that has gone into operation. The appearance of the events changed with increasing energy of the machines and improvements in detectors. The samples become more numerous and more and more decay modes become available.

The history of τ physics started with a handful of events at SPEAR (MARK I), confirmed by the events from DORIS (PLUTO). The energy of DORIS was increased in steps to the $\Upsilon(4s)$ resonance to produce B mesons, but it also was the first machine to provide a large number of τ pairs, recorded by ARGUS. Meanwhile the next generation of accelerators, PEP and PETRA, were built with centre-of-mass energies in the continuum around 30 to 40 GeV and with a number of experiments. Also CESR started running at the $\Upsilon(4s)$ with the CLEO experiment, which today has the largest τ sample. With TRISTAN the Japanese joined, with a machine again in the continuum at 50 to 60 GeV. Despite good luminosity the τ production rate is low, as the cross section falls like $1/s$. In 1989 SLC, and shortly afterwards, LEP began running at the Z^0 boson. BEPC was constructed in Beijing to go back to the τ production threshold and to precisely remeasure, amongst other things, the τ mass. Table 4.1 lists the accelerators that have produced τ pairs and Table 4.2 summarises the experiments that have analysed them.

The set of comprehensive measurements of exclusive hadronic branching ratios from ALEPH [ALEPH98, ALEPH05] and the non-strange spectral functions from ALEPH [ALEPH98, ALEPH05], CLEO [CLEO99] and OPAL [OPAL99] have yielded important contributions to the measurements of $\alpha_s(m_\tau^2)$ and study of perturbative QCD at low energies. Recent measurements of a set of semi-exclusive branching ratios made by DELPHI are also available [De04].

Although no spectral function measurements have yet been presented by the B-factories, BELLE and BABAR, a number of exclusive branching ratio measurements of 3-prong and 5-prong final states from BABAR [So04] are reported. It is evident with this data in hand that work on understanding decay mechanisms and form-factors for these higher multiplicity states is now required.

We have chosen to use the final data from the ALEPH collaboration [ALEPH05] because, as compared to those available from OPAL [OPAL99] and CLEO [CLEO99], they have the smallest experimental errors. Their quality has increased a lot as compared to the earlier ones [ALEPH98]: first, the higher statistics has allowed the

ALEPH collaboration to double the number of bins, and, secondly, the experimental errors decreased due to both higher statistics and a better understanding of systematic errors.

Accelerator	Laboratory	Energy in GeV	Years of operation
SPEAR	SLAC, USA	3 - 8	73 - 88
DORIS	DESY, Germany	8 - 11	77 - 92

4.2 Definitions

The measurement of the τ vector and axial-vector current spectral functions requires the selection and identification of τ decay modes with fixed isotopic G -parity $G = +1$ and $G = -1$, and hence hadronic channels with an even and odd number of neutral or charged pions, respectively. Since hadronic final states of different G -parity differ also in their J^P quantum numbers, there is no interference between these two states. Hence the total hadronic width separates into $\Gamma_{\text{had}} = \Gamma_V + \Gamma_A$.

The spectral functions are obtained by dividing the normalised invariant mass-squared distribution $dR_{\tau,V/A}/ds$ for a given hadronic mass \sqrt{s} by the appropriate kinematic factor. They are then normalised to the branching fraction of the massless leptonic, i.e. electron, channel $\mathcal{B}_e = (17.810 \pm 0.039)\%$ [ALEPH05].

$$\begin{aligned}
 v_1(s) &= \frac{m_\tau^2}{6|V_{ud}|^2 S_{\text{EW}}} \frac{dR_{\tau,V}}{\mathcal{B}_e ds} \left[\left(1 - \frac{2}{m_\tau^2}\right)^2 \left(1 + 2\frac{s}{m_\tau^2}\right) \right]^{-1}, \\
 a_1(s) &= \frac{m_\tau^2}{6|V_{ud}|^2 S_{\text{EW}}} \frac{dR_{\tau,A}}{\mathcal{B}_e ds} \left[\left(1 - \frac{2}{m_\tau^2}\right)^2 \left(1 + 2\frac{s}{m_\tau^2}\right) \right]^{-1}, \\
 a_0(s) &= \frac{m_\tau^2}{6|V_{ud}|^2 S_{\text{EW}}} \frac{dR_{\tau,A}}{\mathcal{B}_e ds} \left(1 - \frac{2}{m_\tau^2}\right)^{-2}.
 \end{aligned} \tag{4.1}$$

Table 4.2: Experiments in τ physics. The number of τ pairs produced, $N_{\tau+\tau^-}$, is given in units of 1000. 'Int. \mathcal{L} ' is the integrated luminosity recorded by the experiment. A typical efficiency for the identification of a τ pair is quoted as ε . Only the running periods relevant to the τ results are listed.

$S_{\text{EW}} = 1.0198 \pm 0.0006$ accounts for short distance electroweak radiative corrections [MS88] and the CKM mixing matrix element has the value $|V_{ud}| = 0.9746 \pm 0.0006$ [DEHZ03]. Due to the conservation of the vector current, there is no $J = 0$ contribution to the vector spectral function, while the only contribution to a_0 is assumed to come from the pion pole. a_0 is connected via partial conservation of the axial-vector current (PCAC) to the pion decay constant f_π through $a_{0,\pi}(s) = 2\pi^2 f_\pi^2 \delta(s - m_\pi^2)$.

4.3 The mass spectra

In this section we will summarise the experimental analysis techniques used by the ALEPH Collaboration as described in Ref. [DHZ06].

The measurement of the τ spectral functions defined in (4.1) requires the determination of the invariant mass-squared distributions, obtained from the experimental distributions after unfolding the effects of measurement distortions. The unfolding procedure used by the ALEPH collaboration follows a method based on the regularised inversion of the simulated detector response matrix using the SVD technique [HK96]. The regularisation function minimises the average curvature of the distribution. The optimal choice of the regularisation strength is found by means of a MC simulation where the true distribution is known and chosen to be close to the expected physical distribution.

To measure exclusive spectral functions, individual unfolding procedures with specific detector response matrices and regularisation parameters are applied for each τ decay channel considered. An iterative procedure is followed to correct the MC spectral functions used to subtract the cross-feed among the modes.

Each spectral function is determined in 140 mass-squared bins of equal width (0.025 GeV²).

All systematic uncertainties concerning the decay classification are contained in the covariance matrix of the branching ratios. Therefore only the systematic effects affecting the shape of the mass-squared distributions, and not its normalisation, need to be examined.

All effects affecting the decay classification and the calculation of the hadronic invariant mass are considered in turn. Comparisons of data and MC distributions are made and the corresponding biases are corrected, while the uncertainty in the correction is taken as input for the calculation of the systematic uncertainty. In the case of the spectral functions, the whole analysis including the unfolding procedure is repeated, for each systematic effect. This generates new mass distributions which are compared bin-by-bin to the nominal ones, hence providing the full 140×140 covariance matrix of the spectral function for the studied effect.

The systematic studies include the effects from the photon and π^0 energy calibration and resolution, the photon detection efficiency, the shape of the identification probability distribution, the estimate of the number of fake photons, the proximity in the calorimeter of other photon showers and of energy deposition by charged particles, and the separation between radiative and π^0 decay photons for residual single photons.

In addition, systematic errors introduced by the unfolding procedure are tested by comparing known, true distributions to their corresponding unfolded ones.

Finally, systematic errors due to the limited MC statistics and to uncertainties in the branching ratios are added.

In order to illustrate the importance of these systematic uncertainties, one may perform an integration over the spectral functions with some given kernel, characteristic of a given physical problem. The integration error is then obtained by Gaussian error propagation taking into account the correlations. Using moderately s -dependent integration kernels, the integration error is dominated by normalisation uncertainties, i.e., the errors on the contributing τ branching ratios. However, the error on an integration with a strongly s -dependent weighting kernel enhancing the low energy parts of the spectral functions is dominated by systematics (mainly due to the fake photon rejection and the photon efficiency correction at threshold), while the central energy region (0.6 - 1.4 GeV²) is statistically limited. When enhancing the higher part of the spectrum, the integration error is equally dominated by uncertainties due to the unfolding process, and by limited data and MC statistics.

4.4 Inclusive non-strange spectral functions

The ALEPH collaboration [ALEPH05] have provided the spectral functions for the hadronic modes, separated into the vector and axial-vector contributions.

Vector and axial-vector spectral functions

The inclusive τ vector and axial-vector spectral functions are shown in Fig.4.1. The solid line depicts the massless perturbative QCD prediction. Although the statistical power of the data is weak near the kinematic limit, the trend of the spectral functions clearly indicates that the asymptotic region [GKL91, SS91] is not reached. The QCD prediction lies roughly 25% (20%) lower (higher) than the data at m_τ^2 for the vector (axial-vector) channel.

To obtain the vector spectral function the two- and four-pion final states were measured exclusively, while the six-pion state was only partly measured. The total six-pion branching fraction has been determined using isospin symmetry from the two- and four-pion ones.

In complete analogy to the vector spectral function the inclusive axial-vector spectral function is obtained by summing up the exclusive axial-vector spectral functions (odd number of pions in the final state), with the addition of small unmeasured modes taken from the MC simulation.

$V \pm A$ spectral functions

For the total $V + A$ hadronic spectral function one does not have to distinguish the properties of the nonstrange hadronic τ decay channels. Hence the mixture of all contributing non-strange final states is measured inclusively.

Figure 4.1: Inclusive vector and axial-vector spectral functions as measured by the ALEPH collaboration [ALEPH05]: (a) Vector spectral function $v_1(s)$; (b) Axial-vector spectral function $a_1(s)$.

Figure 4.2: Inclusive vector plus axial-vector and vector minus axial-vector spectral functions as measured by the ALEPH collaboration [ALEPH05]: (a) Vector plus axial-vector spectral function $v_1(s) + a_1(s)$; (b) Vector minus axial-vector spectral function $v_1(s) - a_1(s)$.

The one, two and three-pion final states dominate and their exclusive measurements are added with proper accounting for (anti-) correlated errors. The remaining contributing topologies are treated inclusively, i.e., without separation of the vector and axial-vector decay modes. The effect of the feed-through between τ final states on the invariant mass spectrum is described by MC simulation and thus corrected in the data unfolding. In this procedure the simulated mass distributions are itera-

tively corrected using the exclusive vector/axial-vector unfolded mass spectra. The $V + A$ spectral function is depicted in Fig.4.2(a). The improvement in precision when comparing to the exclusive sum of the two parts in Fig.4.1 is significant at higher mass-squared values.

One nicely identifies an oscillating behaviour of the spectral function due to resonance contributions. It does also roughly reach (within errors) the asymptotic limit predicted by perturbative QCD at m_τ^2 .

In the case of the $V - A$ spectral function, uncertainties on the V/A separation are reinforced due to their anti-correlation. In addition, anti-correlations given between τ final states with adjacent numbers of pions increase the errors. The $V - A$ spectral function is shown in Fig.4.2(b). The oscillating behaviour of the v_1 and a_1 spectral functions is emphasised but the asymptotic regime seems not to be reached at $s = m_\tau^2$. However, the strong oscillation generated by the hadron resonances mostly averages out to zero, as predicted by perturbative QCD.

Extraction of QCD condensates

Nowadays, it is reliably established that the microscopic theory of the strong interaction is QCD, the gauge theory of interacting quarks and gluons. It is also established, that unlike, e.g., QED, the vacuum in QCD has a nontrivial structure: due to nonperturbative effects, i.e. not admitting the expansion in the interaction constant (even if it is small) there persist non-zero fluctuations of gluonic and quark fields in the QCD vacuum. The nontrivial structure of QCD manifests itself in the presence of vacuum condensates. It is very important to determine these condensates, to study if one can indeed obtain a consistent description of the low energy hadronic physics, to get more insight into the properties of the QCD vacuum, and to confront them to theoretical estimates (from instanton calculus or lattice computation) in order to test the validity of the condensates from experimental data, but also the accuracy of the determination, i.e. to determine their allowed range.

Condensates, in particular quark and gluonic ones, were investigated starting from the 70-ties. Here, first, one should mention the QCD sum rule approach by Shifman, Vainshtein and Zakharov [SVZ79a, SVZ79b], which emphasised the leading role of condensates in the calculation of masses of the low-lying hadronic states. Starting with this pioneering work, a lot of papers were published on the extraction of condensates from experiment. For that purpose one has to relate error affected data in the time-like region to asymptotic QCD in the space-like region. This task of analytic continuation constitutes, mathematically, an ill-posed problem. In fact, extracting condensates from data is highly sensitive to data errors. Not surprisingly, results from different collaborations have not been always consistent.

In what follows we will first discuss general properties of the condensates and briefly review previous extractions. Then, a functional approach for the extraction of condensates from τ -decay data will be presented.

5.1 Condensates: general properties and previous extractions

As already stated in Section 3.5, QCD condensates are vacuum expectation values of gauge invariant scalar operators constructed out of quark and gluon fields. We will review here the familiar ones, describe their properties and give numerical values extracted previously from low-energy and lattice data.

- **Quark condensate:** $\langle \bar{q}q \rangle$

The quark condensate has the lowest dimension ($d = 3$) and it is one of the condensates violating the chiral symmetry. We may rewrite it in the form

$$\langle \bar{q}q \rangle = \langle \bar{q}_L q_R + \bar{q}_R q_L \rangle, \quad (5.1)$$

where q_L, q_R are the fields of left- and right-chiral quarks. As follows from (5.1), a non-zero value of the quark condensate means the transition of left-handed quark fields into right-handed ones and would lead to chiral symmetry violation in QCD. (If chiral symmetry is not violated spontaneously, then non-zero quark masses will induce $\langle \bar{q}q \rangle \neq 0$.)

The quark condensate is related by the Gell-Mann-Oakes-Renner relation [GMOR68] to measurable constants and the quark masses:

$$\langle \bar{q}q \rangle = -\frac{1}{2} \frac{f_\pi^2 m_\pi^2}{m_u + m_d}. \quad (5.2)$$

Here m_π, f_π are the mass and the decay constant of the π^+ -meson ($m_\pi = 140\text{MeV}$, $f_\pi = 131\text{MeV}$), m_u and m_d are the masses of u and d -quarks. For $m_u = 4.2\text{MeV}$, $m_d = 7.5\text{MeV}$, the quark condensate takes the value:

$$\langle \bar{q}q \rangle = -1.4 \times 10^{-2} \text{GeV}^3. \quad (5.3)$$

The value (5.3) has a characteristic hadronic scale. This shows that chiral symmetry, which is satisfied with a good accuracy in the light quark Lagrangian ($m_u, m_d/M \sim 0.01$, M is the hadronic mass scale, $M \sim 0.5 - 1\text{GeV}$), is spontaneously violated in hadronic state spectrum. Due to this fact, the quark condensate may be considered as an order parameter for spontaneous chiral symmetry breaking.

- **Gluon condensate:** $\langle \frac{\alpha_s}{\pi} G_{\mu\nu}^a G_{\mu\nu}^a \rangle$

The gluon condensate has dimension $d = 4$ and was initially introduced by Shifman, Vainshtein and Zakharov in Ref.[SVZ79a] and estimated phenomenologically by different groups in the literature [BB81a, BB81b, Be81, Be88, BLR85, DS88, lo05, KPS84, LNT84, Na95, Na95, Na96, Na98, Na02, Na04, RRY85, SVZ79a, Yn99]. Its value is found to be definitely non-zero and positive. However, results from different groups differ considerably. Some of the results, including the value from Ref.[SVZ79a], do not satisfy the lower bound derived by Bell and Bertlmann [BB81a] from moment sum rules. Recent estimates in [Na04], satisfying this bound from light and heavy quark channels, are of order $(7.1 \pm 0.9) \times 10^{-2} \text{GeV}^4$. We may add the remark that the gluonic condensate conserves chirality.

- **Mixed quark-gluon condensate:** $g\langle\bar{q}G_{\mu\nu}^a\frac{\lambda_a}{2}\sigma^{\mu\nu}q\rangle$

The next in dimension ($d = 5$) is the mixed quark-gluon condensate which has the form:

$$g\langle\bar{q}G_{\mu\nu}^a\frac{\lambda_a}{2}\sigma^{\mu\nu}q\rangle \equiv m_0^2\langle\bar{q}q\rangle. \quad (5.4)$$

The value of the parameter m_0^2 has been estimated from baryon sum rules [Bl82, Ch81, Ch82, lo81a, lo81b], the $B - B^*$ mass splitting [Na88b], a string model [GS04] and lattice calculations, with a fair agreement. Note that the mixed quark-gluon condensate is also violating the chiral symmetry.

- **Four-quark condensate:** $\langle\bar{q}\Gamma_1q\bar{q}\Gamma_2q\rangle$

The general form of the dimension $d = 6$ four-quark condensate is as follows:

$$\langle\bar{q}\Gamma_1q\bar{q}\Gamma_2q\rangle, \quad (5.5)$$

where Γ_1, Γ_2 are combinations of Dirac matrices. Following [SVZ79a, SVZ79b], Eq.(5.5) is usually factorized, and in the sum over intermediate states in all channels only the vacuum state is taken into account. The accuracy of such an approximation is $\sim 1/N_c^2$, with N_c the number of colours, i.e., $\sim 10\%$. After factorisation, Eq.(5.5) reduces to

$$\langle\bar{q}q\rangle^2. \quad (5.6)$$

The four-quark condensate was estimated from different channels [CSSS04, LNT84, Na04]. The corresponding results indicate a violation of the factorisation assumption by at least a factor of 2.

- **Triple gluon condensate:** $\langle g^3 f_{abc} G^a G^b G^c \rangle$

The triple gluon condensate ($d = 6$) was originally estimated by Shifman, Vainshtein and Zakharov [SVZ79a] using an instanton liquid model. Its value was confirmed later by lattice calculations [GR81, GGP83].

- **Higher-order condensates**

The dimension $d = 8$ and higher dimension condensates were estimated in the V [Na95], $V + A$ and $P + S$ [Na01] channels using experimental and lattice data [De01].

More recently, condensates of the $V - A$ channel have been estimated from τ -decay data [ALEPH98, ASS07, BDPS06, CGM03, CSSS04, DS04, IZ01, Na05, OPAL99, RL04, Zy04] and from QCD at large N_c [FGR04]. Large violations of the vacuum saturation estimates of these condensates have been observed also in these analyses.

5.2 The method: a functional approach

In what follows we will study a functional method¹, introduced in Ref. [CSSS04], which allows, in principle, to extract the condensates within rather general assumptions.

For our purpose, let us consider a set of functions $F(s)$ which are admissible as a representation of the true amplitude if they are real analytic functions in the complex s -plane cut along the time-like interval $[s_0, \infty)$. The asymptotic behaviour of $F(s)$ is restricted by fixing the number of subtractions in the dispersion relation between $F(s)$ and its imaginary part $f(s) = \text{Im}F(s + i0)$ along the cut

$$F(s) = \frac{1}{\pi} \int_{s_0}^{\infty} K(s, z) f(z) dz + \text{subtractions} . \quad (5.7)$$

In general, $K(s, z)$ is the usual Cauchy kernel but we prefer this more general notation since later on we will use also more complex kernels, e.g. derivatives of the Cauchy kernel.

In order to determine $F(s)$ and $f(s)$ we use the following two available sources of information:

- experimental data measured in the time-like interval $\Gamma_{\text{exp}} = [s_0, s_{\text{max}}]$, $s_0 > 0$: $f_{\text{exp}}(s)$;
- theoretical model given by perturbative QCD, i.e.,
 - the prediction for $F(s)$ in the space-like interval $\Gamma_L = [s_2, s_1]$: $F_{QCD}(s)$
 - and $f_{QCD}(s) = \text{Im}F_{QCD}(s + i0)|_{s \in (s_{\text{max}}, \infty)}$ since QCD is expected to be reliable for large energies.

As a next step in extracting values for the condensates, we split the integral on the r.h.s. of the dispersion relation (5.7) into two parts: one that can be described by the experiment and the other one by the theoretical model, i.e., QCD:

$$\underbrace{F_{QCD}(s) - \frac{1}{\pi} \int_{s_{\text{max}}}^{\infty} K(s, z) f_{QCD}(z) dz}_{\text{QCD prediction: } \tilde{F}_{QCD}(s)} = \underbrace{\frac{1}{\pi} \int_{s_0}^{s_{\text{max}}} K(s, z) f(z) dz}_{\text{experiment}} . \quad (5.8)$$

The goal of the method is to check if there exists a function $F(s)$ which is in accord with both the data on Γ_{exp} and the model on Γ_L . For doing this, one can use an L^2 -norm² approach and define two functionals $\chi_L^2[f]$ and $\chi_R^2[f]$. $\chi_R^2[f]$ compares the true amplitude $f(s)$ with the data. Using its covariance matrix as a weight function, we can define:

$$\chi_R^2[f] = \frac{1}{|\Gamma_{\text{exp}}|} \int_{s_0}^{s_{\text{max}}} dx \int_{s_0}^{s_{\text{max}}} dx' V^{-1}(x, x') (f(x) - f_{\text{exp}}(x))(f(x') - f_{\text{exp}}(x')). \quad (5.9)$$

¹The functional method underlying the analysis has first been described in [AM89, ACM90, CM90].

²The L^2 -norm is defined as: $\|f\|^2 \equiv (f, f) = \int |f(x)|^2 dx$.

As a measure for the agreement of the true function $f(s)$ with the theory, we define $\chi_L^2[f]$ by comparing the left and right hand sides of (5.8)

$$\chi_L^2[f] = \frac{1}{|\Gamma_L|} \int_{\Gamma_L} w_L(x) \left(\tilde{F}_{QCD}(x) - \frac{1}{\pi} \int_{s_0}^{s_{\max}} K(x, x') f(x') dx' \right)^2 dx, \quad (5.10)$$

where w_L is a weight function for the space-like interval, i.e. an *a-priori* estimate of the accuracy of the QCD predictions and identified with $1/\sigma_L^2(s)$. $\sigma_L(s)$ is a continuous, strictly positive function of $s \in \Gamma_L$ which should encode errors due to the truncation of the perturbative series and the OPE. It is expected to decrease as $|s| \rightarrow \infty$ and diverge for $s \rightarrow 0$.

In order to find the true function $f(s)$ one can combine the information contained in these two functionals by means of Lagrange multipliers and find the unrestricted minimum of

$$\mathcal{F}[f] = \chi_L^2[f] + \mu \chi_R^2[f], \quad (5.11)$$

subject to the condition

$$\chi_R^2[f] \leq \chi_{\text{exp}}^2 = \frac{1}{N} \sum_{i,j} \sqrt{V(s_i, s_i) V(s_j, s_j) V^{-1}(s_i, s_j)}, \quad (5.12)$$

which will be the criteria to determine the Lagrange multiplier μ . This procedure leads to an integral equation for the imaginary part of the true amplitude, $f(x; \mu)$ [CSSS04]:

$$\begin{aligned} f(x; \mu) = f_{\text{exp}}(x) + \frac{\lambda |\Gamma_{\text{exp}}|}{\pi |\Gamma_L|} \int_{s_0}^{s_{\max}} dy V(y, x) \int_{\Gamma_L} dx' w_L(x') K(x', y) \tilde{F}_{QCD}(x') \\ + \lambda \int_{s_0}^{s_{\max}} dx' K_2(x, x') f(x'; \mu), \end{aligned} \quad (5.13)$$

where $\lambda = 1/\mu$ and

$$K_2(x, x') = -\frac{|\Gamma_{\text{exp}}|}{\pi^2 |\Gamma_L|} \int_{s_0}^{s_{\max}} dy V(y, x) \int_{\Gamma_L} dz w_L(z) K(z, y) K(z, x'). \quad (5.14)$$

The size of σ_L determines the minimal value of χ_L^2 according to Eq.(5.10) that can be reached by this algorithm. Obviously, widening the error corridor (increasing σ_L) will lead to values for $\chi_{L, \min}^2$ as small as desired. In such a case, the information obtained from the fit is not conclusive, since any model function $f(s)$ can be made consistent with the data if one allows for a wide enough error corridor. On the other hand, narrowing the error corridor will increase $\chi_{L, \min}^2$, signalling a bad fit, i.e., bad consistency of theory with data if the model function is not perfectly describing the data. However, a nontrivial result of our approach is the fact, that there exists a choice for the error corridor that leads to values $\chi_{L, \min}^2 = \mathcal{O}(1)$. We shall assume

V – A analysis

The $V - A$ correlator, $\Pi_{V-A}^{(0+1)} = \Pi_V^{(1)} - \Pi_A^{(1)} - \Pi_A^{(0)}$, is of particular interest, since it contains no truly perturbative contribution in the massless quark limit and it is entirely described by the OPE expansion.

To apply the method described in Section 5.2 to the $V - A$ channel, we identify $F(s)$ with $\Pi_{V-A}^{(0+1)}(s)$. We will use the appropriate combination of spectral functions, $v_1(s) - a_1(s) - a_0(s)$ as the experimental information. The spin-0 axial spectral function, $a_0(s)$, is basically saturated by the $\tau \rightarrow \pi\nu_\tau$ channel (see Section 4.2) and can thus be taken into account separately. Inserting this into the dispersion relation (5.7) one finds:

$$F(s) = \frac{1}{\pi} \int_{s_0}^{\infty} dz K(s, z) f(z) + \frac{f_\pi^2}{s}, \quad (6.1)$$

with

$$K(s, z) = \frac{1}{z - s}. \quad (6.2)$$

Note that for the $V - A$ correlator no subtractions are needed. The term f_π^2/s comes from the pion pole; $f_\pi = 0.1307$ GeV [PDG06] is the pion decay constant.

So, one has the information:

$$f_{\text{exp}}(s) = \frac{1}{2\pi} [v_1(s) - a_1(s)], \quad (6.3)$$

$$F_{QCD}(s) = \Pi_{V-A}^{(0+1)}(s) = \sum_{d \geq 6} \frac{\mathcal{O}_d^{V-A}}{(-s)^{d/2}} \left(1 + c_D^{NLO} \frac{\alpha_s(\mu^2)}{\pi} + O(\alpha_s^2) \right) \quad (6.4)$$

which can be used for the extraction of condensates. The QCD prediction, $\tilde{F}_{QCD}(s)$, will then be:

$$\tilde{F}_{QCD}(s) = F_{QCD}(s) - \frac{f_\pi^2}{s} - \frac{1}{\pi} \int_{s_{\text{max}}}^{\infty} K(s, z) f_{QCD}(z) dz. \quad (6.5)$$

The complete expression for \mathcal{O}_6^{V-A} is known to involve two operators [CDGM01, CDGM03]. Assuming vacuum dominance or the factorisation approximation which

holds, e.g., in the large- N_C limit, the matrix elements can be written:

$$\begin{aligned}\mathcal{O}_6^{V-A} &= -\frac{64\pi}{9}\alpha_s\langle\bar{q}q\rangle^2, \quad c_6^{NLO} = \frac{1}{4}\left[\tilde{c}_6 + \ln\left(\frac{\mu^2}{-s}\right)\right], \\ \mathcal{O}_8^{V-A} &= -4\pi\alpha_s i(1 - N_C^{-2})\langle\bar{q}q\rangle\langle\bar{q}\gamma^{\alpha\beta}G_{\alpha\beta}q\rangle, \\ \mathcal{O}_{10}^{V-A} &= -\frac{8}{9}\pi\alpha_s\langle\bar{q}q\rangle^2\left(\frac{50}{9}m_0^4 + 32\pi\alpha_s\langle G_{\alpha\beta}G^{\alpha\beta}\rangle\right).\end{aligned}\tag{6.6}$$

However, our analysis does not rely on the factorisation hypothesis since we are going to determine \mathcal{O}_d^{V-A} , but not the condensates separately. In the result for \mathcal{O}_{10}^{V-A} [Zy04], m_0^2 is defined through the 5-dimensional quark-gluon mixed condensate. Starting from the second order, coefficients in perturbation theory depend on the regularisation scheme implying that the value of the condensates are scheme-dependent quantities. The NLO corrections c_6^{NLO} for \mathcal{O}_6^{V-A} were computed in [LSC86] and the constant \tilde{c}_6 was found equal to 247/12. This calculation was based on the Breitenlohner-Maison definition of γ^5 in dimensional regularisation. A different treatment of γ^5 as used in Ref. [AC94] leads to $\tilde{c}_6 = 89/12$.

Since the $V - A$ correlator is entirely given by OPE terms and has no truly perturbative contribution, we will take as an error estimate the next higher dimension contribution in the OPE, depending on the condensates one wants to determine.

6.1 1-parameter fit: determination of \mathcal{O}_6^{V-A}

We start with a discussion of results obtained by 1-parameter fits of the dimension $d = 6$ condensate. We have chosen the dimension $d = 8$ contribution to define the error channel on the space-like region, i.e. $\sigma_L(s) = |\mathcal{O}_8^{V-A}|_{\max}/s^4$ with $|\mathcal{O}_8^{V-A}|_{\max}$ in the order of 10^{-3}GeV^8 .

6.1.1 \mathcal{O}_6^{V-A} at leading-order

We have performed first the fit for the leading-order (LO) dimension $d = 6$ condensate, i.e., we have treated \mathcal{O}_6^{V-A} in (6.6) as a constant and took $c_6^{NLO} = 0$. The corresponding QCD amplitude, and its imaginary part, are then:

$$F_{QCD}(s) = \frac{\mathcal{O}_6^{V-A}}{(-s)^3}, \quad f_{QCD}(s) = 0.\tag{6.7}$$

A typical situation resulting from this algorithm is shown in Fig.6.1. χ_L^2 has indeed a minimum and at least in the vicinity of this minimum it has the expected quadratic dependence on \mathcal{O}_6^{V-A} (Fig.6.1(a)). The regularised function (Fig.6.1(b)) follows nicely the data points, except at large s , as it is well illustrated by Fig.6.1(c) where the difference between experimental data and the regularised function is plotted. One can show that the information on the condensate is contained in the lower part of the spectrum by adding or removing data-points contained in the saturated

upper part: this would not change the result (Fig.6.2, left panel). Thus, the discrepancies between data and the regularised function at large s , mainly due to larger errors in the data, play no role for the determination of \mathcal{O}_6^{V-A} .

Figure 6.1: A typical result of the algorithm: (a) χ_L^2 [Eq.(5.10)] as a function of \mathcal{O}_6^{V-A} ; (b) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (c) difference between data and the regularised function. We have chosen for the error parameter $\mathcal{O}_8^{V-A} = 1.5 \times 10^{-3} \text{ GeV}^8$.

Figure 6.2: \mathcal{O}_6^{V-A} as a function of the number N of data points used in the analysis (e.g. $N = 120$ means that the data points used in the analysis are the first 120) (left) and of s_1 , the upper limit of the space-like interval Γ_L (right).

We have restricted the integration range in χ_L^2 within the limits $s_2 \leq s \leq s_1 \leq 0$. We have observed a well-defined plateau for the value of \mathcal{O}_6^{V-A} as a function of s_1 between -1.5 and 0 GeV^2 (Fig.6.2, right panel) and quote the results for $s_1 = -1.0$ GeV^2 .

We have also studied the behaviour of the algorithm with respect to changes of the lower limit, s_2 . In principle, one could choose s_2 to be minus infinity but, as one can see in Fig.6.3, we are forced to choose a finite value. The figure on the right shows us that the value of $|s_2|$ for which we still have agreement between data and experiment is in the order of 10^2 . For larger values, the minimum of χ_L^2 (Eq.(5.10)) becomes larger than 1 and thus signalling a bad fit (for more details see Appendix D). The reason for this inconsistency, for values of $|s_2|$ larger than $O(10^2)$, could lie in the assumption of the decoupling of heavy quarks. The heavy quarks could play an important role at sufficiently high energies. There are also other reasons, like numerical instabilities and rounding errors. However, there exists a plateau for the value of \mathcal{O}_6^{V-A} as a function of s_2 between -10GeV^2 and -300GeV^2 . In the rest of the analysis we have quoted results for $s_2 = -150\text{GeV}^2$.

Figure 6.3: Dependence on the lower end of the space-like interval, s_2 : \mathcal{O}_6^{V-A} as a function of s_2 (left); $\chi_{L,\min}^2$ as a function of s_2 , on a log-log scale (right).

The dimension $d = 8$ condensate \mathcal{O}_8^{V-A} was used only to define the error channel in the space-like region and thus we expect that the resulting central value of \mathcal{O}_6^{V-A} does not depend strongly on $|\mathcal{O}_8^{V-A}|_{\max}$, which is indeed reflected in the plot of Fig.6.4. However, increasing $|\mathcal{O}_8^{V-A}|_{\max}$, i.e., opening the error channel, leads to larger uncertainties for \mathcal{O}_6^{V-A} . A value of $\chi_{L,\min}^2$ corresponding to a 1σ CL can be fixed by choosing an error corridor described by the contribution from an \mathcal{O}_8^{V-A} condensate of the expected size of $\simeq 1.3 \times 10^{-3} \text{GeV}^8$. The results of the 1-parameter fit at LO can be summarised by quoting the value for \mathcal{O}_6^{V-A} [ASS07]:

$$\mathcal{O}_6^{V-A} = -5.9_{-1.0}^{+1.7} \times 10^{-3} \text{GeV}^6 \text{ for } \tilde{c}_6 = 0. \quad (6.8)$$

The value of \mathcal{O}_6^{V-A} can be translated into values for the 4-quark condensate $\alpha_s \langle \bar{q}q \rangle^2$:

$$\alpha_s \langle \bar{q}q \rangle^2 = 2.64_{-0.76}^{+0.44} \times 10^{-4} \text{GeV}^6. \quad (6.9)$$

as given by Eq.(6.6). This value can be compared with the lowest order vacuum saturation expression

$$\alpha_s \langle \bar{q}q \rangle^2 \simeq 2.78 \times 10^{-4} \text{GeV}^6, \quad (6.10)$$

where we have used for the quark condensate the value of Eq.(5.3).

Figure 6.4: Dependence on the error parameter for the LO analysis: \mathcal{O}_6^{V-A} as a function of \mathcal{O}_8^{V-A} .

6.1.2 \mathcal{O}_6^{V-A} at next-to-leading-order

In what follows we are interested in studying the influence of NLO corrections to \mathcal{O}_6^{V-A} and check if the results based on the NLO formula are in agreement with the ones found in the last section. For this purpose one needs to consider the NLO corrections in (6.6) and treat \mathcal{O}_6^{V-A} as a constant like before. With the NLO corrections included, the corresponding QCD amplitude and its imaginary part are:

$$F_{QCD}(s) = \frac{\mathcal{O}_6^{V-A}}{(-s)^3} \left\{ 1 + \tilde{c}_6 \frac{\alpha_s(-s)}{4\pi} \right\}, \quad (6.11)$$

$$f_{QCD}(s) = \frac{\mathcal{O}_6^{V-A}}{(-s)^3} \frac{\alpha_s(s)}{4}.$$

The renormalization scale μ^2 was conveniently chosen to be $|s|$.

A typical result is seen in Fig.6.5. Here, one should remark that the discrepancies between experimental data and the regularised function are still present. One can

thus conclude that including NLO corrections does not improve the quality of our fit. The central value of \mathcal{O}_6^{V-A} is now shifted with respect to the one from the LO fit, Eq.(6.8), which was to be expected (Fig.6.6). All the consistency checks (see Figs. 6.2 and 6.3) performed for the LO fit remain valid.

Figure 6.5: A typical result of the algorithm for the NLO analysis: (a) χ_L^2 [Eq.(5.10)] as a function of \mathcal{O}_6^{V-A} ; (b) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (c) difference between data and the regularised function. We have chosen for the error parameter $\mathcal{O}_8^{V-A} = 1.5 \times 10^{-3} \text{GeV}^8$ and $\tilde{c}_6 = 89/12$.

Figure 6.6: Dependence on the error parameter for the NLO analysis with $\tilde{c}_6 = 247/12$: \mathcal{O}_6^{V-A} as a function of \mathcal{O}_8^{V-A} .

We can now summarise the results of the NLO fit and quote values for \mathcal{O}_6^{V-A} for the two available values of the NLO coefficients [ASS07]:

$$\begin{aligned}\mathcal{O}_6^{V-A} &= -4.9_{-1.1}^{+1.5} \times 10^{-3} \text{GeV}^6 \text{ for } \tilde{c}_6 = 89/12, \\ \mathcal{O}_6^{V-A} &= -3.6_{-1.2}^{+1.1} \times 10^{-3} \text{GeV}^6 \text{ for } \tilde{c}_6 = 247/12.\end{aligned}\tag{6.12}$$

The results are based on the 4-loop expression for α_s with $\Lambda_{\overline{MS}}(N_f = 3) = 0.326 \text{GeV}$. They are not sensitive to changing $\Lambda_{\overline{MS}}$ within the present experimental error of $\pm 0.030 \text{GeV}$. Moreover, the fit results based on the two different values of the NLO coefficients \tilde{c}_6 agree within errors and their difference with respect the LO result, Eq.(6.8), is consistent with a shift calculated from the correction term choosing a typical value of $\mathcal{O}(1.5) \text{GeV}$ for the renormalization scale in α_s . This is to be expected since our method would work for any s -dependent ansatz for \mathcal{O}_6^{V-A} as well.

We have found agreement of theory and data at the $1\sigma\text{CL}$ for the dimension $d = 8$ contribution describing the error with the value $\simeq 1.3 \times 10^{-3} \text{GeV}^8$.

The values of \mathcal{O}_6^{V-A} from Eq.(6.12) translate into values for the 4-quark condensate $\alpha_s \langle \bar{q}q \rangle^2$ according to Eq.(6.6):

$$\begin{aligned}\alpha_s \langle \bar{q}q \rangle^2 &= 2.19_{-0.67}^{+0.49} \times 10^{-4} \text{GeV}^6 \text{ for } \tilde{c}_6 = 89/12, \\ \alpha_s \langle \bar{q}q \rangle^2 &= 1.61_{-0.49}^{+0.54} \times 10^{-4} \text{GeV}^6 \text{ for } \tilde{c}_6 = 247/12.\end{aligned}\tag{6.13}$$

The values are consistent with the one from the LO analysis, Eq.(6.9), as well as with that of the vacuum saturation expression (6.10).

6.2 2-parameter fit: $\mathcal{O}_6^{V-A} - \mathcal{O}_8^{V-A}$ correlation

An interesting and new result is obtained from a 2-parameter fit of the dimension $d = 6$ and $d = 8$ condensates. Here we do not include the NLO contribution to \mathcal{O}_6^{V-A} since the corresponding NLO coefficient for \mathcal{O}_8^{V-A} is not known. To define the error corridor on the space-like region we have used the dimension $d = 10$ contribution to the operator product expansion and set:

$$\sigma_L(s) = |\mathcal{O}_{10}^{V-A}|_{\text{max}} / (-s)^5\tag{6.14}$$

with $|\mathcal{O}_{10}^{V-A}|_{\text{max}}$ in the order of 10^{-3}GeV^{10} .

We will not repeat all the consistency checks performed in the 1-parameter case. We may argue that they will be qualitatively not changed. Keeping the parameters at the quoted values (see Section 6.1.1), one finds a typical result as the one of Fig.6.7. A direct comparison of experimental data with the regularised function $f(s)$ (see Fig.6.7(a)) shows a nice agreement over the full range of s with the exception of the highest s -bins. Nevertheless, we have learned from the 1-parameter fits that this is due mainly to large experimental errors and that it does not play a sensible role in determining the condensates.

Figure 6.7: A typical result of the 2-parameter fit (LO): (a) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (b) difference between data and the regularised function; (c) 1- and 2σ confidence regions in the $(\mathcal{O}_6^{V-A}, \mathcal{O}_8^{V-A})$ -plane; The central values are marked by dashed lines. (d) χ_L^2 [Eq.(5.10)] as a function of \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} . The error parameter was set to $|\mathcal{O}_{10}^{V-A}|_{\max} = 4 \times 10^{-3} \text{GeV}^{10}$.

Figure 6.8: 1- and 2 σ confidence regions in the $(\mathcal{O}_6^{V-A}, \mathcal{O}_8^{V-A})$ -plane for different values of the error parameter $|\mathcal{O}_{10}^{V-A}|_{\max}$. The central values are marked by dashed lines.

The plot in Fig.6.7(d) shows that χ_L^2 has the expected quadratic dependence on the parameters \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} , at least in the vicinity of the minimum. However, a more convenient way to visualise χ_L^2 are contour plots, i.e., lines of constant values of χ_L^2 projected on the $(\mathcal{O}_6^{V-A}, \mathcal{O}_8^{V-A})$ -plane. Fig.6.7(c) shows such contour lines corresponding to 1- and 2σ confidence regions (CR) for the two parameters (see Appendix D.2 for the way the confidence regions are defined and constructed).

As expected, the confidence region becomes larger as we open the error corridor, i.e. increase $|\mathcal{O}_{10}^{V-A}|_{\max}$, but the central values of \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} corresponding to the absolute minimum of χ_L^2 remain the same within errors. This is well illustrated in Fig.6.8. One can observe that the islands which appear for $|\mathcal{O}_{10}^{V-A}|_{\max} = 1 \times 10^{-3} \text{ GeV}^{10}$ become larger and transform into approximative ellipses as we increase $|\mathcal{O}_{10}^{V-A}|_{\max}$ and for sufficiently large $|\mathcal{O}_{10}^{V-A}|_{\max}$ they become parallelogram like. This specific change in the shape has no physical meaning, but rather shows that at large values of \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} the underlying probability distribution function is not Gaussian, χ_L^2 having a quadratic dependence on the two parameters only in a small neighbourhood of its minimum.

Figure 6.9: 1- and 2σ confidence regions in the $(\mathcal{O}_6^{V-A}, \mathcal{O}_8^{V-A})$ -plane from the LO 2-parameter fit at the 1σ CL agreement of theory and data. The central values are marked by dashed lines.

The nontrivial result is that we find agreement of theory and data at the 1σ CL if we choose $|\mathcal{O}_{10}^{V-A}|_{\max} \simeq 5.7 \times 10^{-3} \text{ GeV}^{10}$. The result presented in Fig.6.9 shows a strong correlation of \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} . Both the central values as well as the errors from the 2-parameter fit are consistent with those from the LO 1-parameter analysis: The 1σ range allowed for \mathcal{O}_6^{V-A} for fixed $\mathcal{O}_8^{V-A} = 0$ (which is the assumption underlying the 1-parameter fit) agrees with (6.8) and (6.12). However, leaving the value of \mathcal{O}_8^{V-A} unconstrained, as is the case here, one finds a much larger range for

\mathcal{O}_6^{V-A} . The minimum value of χ_L^2 is located at the values:

$$\begin{aligned}\mathcal{O}_6^{V-A} &= -6.8_{-0.8}^{+2.0} \times 10^{-3} \text{ GeV}^6, \\ \mathcal{O}_8^{V-A} &= 3.2_{-9.2}^{+2.8} \times 10^{-3} \text{ GeV}^8.\end{aligned}\tag{6.15}$$

The errors on \mathcal{O}_6^{V-A} for fixed \mathcal{O}_8^{V-A} are small, but the allowed range for \mathcal{O}_8^{V-A} is not very restrictive (note the different scales for the two coordinate axes in Fig.6.9). However, the strong correlation allows one to determine a linear combination of \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} with a rather small error [ASS07]:

$$\mathcal{O}_8^{V-A} + 2.22 \text{ GeV}^2 \mathcal{O}_6^{V-A} = -18.30_{-0.25}^{+0.38} \times 10^{-3} \text{ GeV}^8\tag{6.16}$$

This is an important result. If one would know one of the parameters from an independent determination, one could specify the value of the other one with well defined small errors in the order of 3%.

Figure 6.10: 1- and 2 σ confidence regions in the $(\mathcal{O}_6^{V-A}, \mathcal{O}_8^{V-A})$ -plane from the NLO 2-parameter fit at the 1 σ CL agreement of theory and data. The central values are marked by dashed lines.

We have also checked that we obtain consistent results when including the NLO correction to \mathcal{O}_6^{V-A} : The 1- and 2 σ contours are shifted, essentially without changing their form (Fig.6.10), to larger values of \mathcal{O}_6^{V-A} exactly as can be inferred from the 1-parameter fits: for $\tilde{c}_6 = 0(89/12, 247/12)$ we find the minimum of χ_L^2 at $\mathcal{O}_6^{V-A} \times 10^3 / \text{GeV}^6 = -6.8(-6.6, -5.8)$.

The linear combinations of \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} for the two available NLO coefficients are then:

$$\begin{aligned}\mathcal{O}_8^{V-A} + 2.69 \text{ GeV}^2 \mathcal{O}_6^{V-A} &= -14.40_{-0.29}^{+0.16} \times 10^{-3} \text{ GeV}^8 \quad \text{for } \tilde{c}_6 = 89/12, \\ \mathcal{O}_8^{V-A} + 4.07 \text{ GeV}^2 \mathcal{O}_6^{V-A} &= -20.80_{-0.20}^{+0.20} \times 10^{-3} \text{ GeV}^8 \quad \text{for } \tilde{c}_6 = 247/12.\end{aligned}\tag{6.17}$$

They are consistent with the LO result and have even smaller errors.

6.3 Review and comparison of results

There exists a number of previous extractions of QCD condensates in the literature, mainly based on sum rule approaches and at LO. They are listed in Table 6.1. There also exist previous extractions at NLO, based on the same functional approach as in this work, listed in Table 6.2.

The results for \mathcal{O}_6^{V-A} cover values between $(-2.27 \pm 0.51) \times 10^{-3} \text{ GeV}^6$ [CGM03] and $(-8.7 \pm 2.3) \times 10^{-3} \text{ GeV}^6$ [Na05]. These values correspond to a scale of about 200 MeV which is comparable to Λ_{QCD} . Although errors given by the respective authors are typically in the order of 25%, their central values are only in rough agreement. The observed variations of these results represent the ambiguities inherent in the QCD sum rule approach. Our result nicely falls into the same range, also with an error estimate of the same size.

For \mathcal{O}_8^{V-A} , previous results range from $(-10.8 \pm 6.6) \times 10^{-3} \text{ GeV}^8$ [BDPS06] to $(15.6 \pm 4.0) \times 10^{-3} \text{ GeV}^8$ [Na05]. A recent conservative estimate [RL04] is $\mathcal{O}_8^{V-A} = (-12_{-11}^{+7}) \times 10^{-3} \text{ GeV}^8$. Again, our result agrees within the estimated precision. The same is true for \mathcal{O}_{10}^{V-A} for which previous results range from $(-17.1 \pm 4.4) \times 10^{-3} \text{ GeV}^{10}$ [Na05] to $(78 \pm 24) \times 10^{-3} \text{ GeV}^{10}$ [RL04]. The spread of values found in the literature for the $d = 12$ condensate, \mathcal{O}_{12}^{V-A} , is even larger: from $(-240 \pm 100) \times 10^{-3} \text{ GeV}^{12}$ [BDPS06] to $(14.7 \pm 3.7) \times 10^{-3} \text{ GeV}^{10}$ [Na05] as one can read off from Table 6.1. These values are also consistent with the values we had to choose for the error corridor.

Moreover, it is also interesting to note the agreement of the correlation between \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} with corresponding results from [Na05, Zy04]. In Ref. [Na05], this correlation is extracted from weighted finite energy sum rules but no errors are given while in Ref. [Zy04] Borel sum rules were used. In the latter, 1-, 2- and 3σ confidence regions for the correlations $\mathcal{O}_6^{V-A}-\mathcal{O}_8^{V-A}$ and $\mathcal{O}_6^{V-A}-\mathcal{O}_{10}^{V-A}$ are presented. The 1σ allowed ranges for \mathcal{O}_6^{V-A} and \mathcal{O}_8^{V-A} are shifted as compared to ours, but the slope agrees well within errors.

Obviously, our numerical results are, from a practical point of view, not superior to approaches based on finite energy sum rules. However, the fact that we find agreement within errors is not trivial. Since this approach is based on much more general assumptions, the results obtained in our analysis give additional confidence to the numerical values obtained with the help of QCD sum rules.

V , A and $V + A$ analysis

The final precise data on the non-strange hadronic spectral functions from ALEPH [ALEPH05] allows us to perform also an analysis in the $V + A$, V and A channels separately.

Since the V , A and $V + A$ correlators are dominated by their perturbative contributions, there are subtractions needed in the dispersion relation (5.7), the starting point of our analysis. However, as stated in Section 3.6, one can eliminate these subtractions by taking an appropriate number of derivatives of the correlator in question. For V , A and $V + A$ there is only one subtraction and thus one needs to take only the first derivative and write

$$F(s) = -\frac{1}{\pi} \int_{s_0}^{\infty} dx K(s, x) f(x), \quad (7.1)$$

where now

$$F(s) = -s \frac{d}{ds} \Pi_{V,A,V+A}(s), \quad (7.2)$$

$$K(s, x) = \frac{s}{(x-s)^2}, \quad (7.3)$$

and

$$f(x) = \text{Im} \Pi_{V,A,V+A}(x) \quad (7.4)$$

is the same as before.

According to (3.27), one has:

$$F(s) = D_{V,A,V+A}(s) + \sum_{d \geq 4} \frac{d}{2} \frac{\mathcal{O}_d^{V,A,V+A}}{(-s)^{d/2}} (1 + O(\alpha_s)). \quad (7.5)$$

The Adler function, $D(s)$, is known in the massless-quark limit up to terms of order α_s^4 and reads:

$$D_{V,A}(s) = \frac{1}{4\pi^2} \sum_{n \geq 0}^4 K_n \left(\frac{\alpha_s(s)}{\pi} \right)^n. \quad (7.6)$$

The coefficients K_n are the same for both A and V channels. For 3 flavours, in $\overline{\text{MS}}$ regularisation, $K_0 = K_1 = 1$, $K_2 = 1.64$ [CKT79, CG80, DS79], $K_3 = 6.37$

[GKL91, SS91] and for K_4 there are two estimates $K_4 = 25 \pm 25$ [KS95] and $K_4 = 27 \pm 16$ [BCK03].

The experimental information we use are the appropriate spectral functions, i.e., $v_1(s)$ for the V channel, $a_1(s) + a_0(s)$ for the A channel and $v_1(s) + a_1(s) + a_0(s)$ for the $V + A$ one. As seen in Section 4.2, $a_0(s)$ is basically saturated by the pion pole and thus we will take it into account separately, as we did before.

The QCD prediction on the time-like interval (s_{\max}, ∞) is given by the perturbative expansion:

$$f_{QCD}^{V,A} = \frac{1}{4\pi} \left(1 + \frac{\alpha_s(x)}{\pi} + O(\alpha_s^2) \right). \quad (7.7)$$

To summarise, the QCD information that we have at hand, i.e., the l.h.s. of Eq.(5.8), is:

$$F_{QCD}^V(x) = D^V(x) + \sum_{d \geq 4} \frac{d}{2} \frac{\mathcal{O}_d^V}{(-x)^{d/2}} \left(1 + c_{d,V}^{NLO} \frac{\alpha_s(\mu^2)}{\pi} \right), \quad (7.8)$$

$$F_{QCD}^A(x) = D^A(x) + \sum_{d \geq 4} \frac{d}{2} \frac{\mathcal{O}_d^A}{(-x)^{d/2}} \left(1 + c_{d,A}^{NLO} \frac{\alpha_s(\mu^2)}{\pi} \right) + \frac{f_\pi^2}{x}. \quad (7.9)$$

Obviously, for $F_{QCD}^{V+A}(x)$ one has to sum the two equations.

Assuming vacuum dominance, as in the case of the $V - A$ correlator, the $V + A$ matrix elements can be written as:

$$\begin{aligned} \mathcal{O}_4^{V+A} &= \frac{\alpha_s}{6\pi} \langle G_{\mu\nu}^a G_{\mu\nu}^a \rangle, & c_{4,V+A}^{NLO} &= \frac{7}{6}, \\ \mathcal{O}_6^{V+A} &= \frac{128}{81} \pi \alpha_s \langle \bar{q}q \rangle^2, & c_{6,V+A}^{NLO} &= \frac{29}{24} + \frac{17}{18} \ln \frac{-s}{\mu^2}. \end{aligned} \quad (7.10)$$

The coefficients for the α_s -corrections were calculated in [CGS85] and [AC94], respectively. Considering these matrix elements together with those from the $V - A$ channel, Eq.(6.6), one can easily find similar representations for $\mathcal{O}_d^{V,A}$. However, as before, our analysis does not rely on such representations since we aim to determine $\mathcal{O}_d^{V,A,V+A}$ and not the condensates $\langle G_{\mu\nu}^a G_{\mu\nu}^a \rangle$, $\langle \bar{q}q \rangle^2$ separately.

For the error corridor one can use the last known term of the perturbation series possibly combined with the first omitted term in the series over condensates.

7.1 A analysis

Let us start with the analysis of the axial-vector channel and perform 1- and 2-parameter fits in order to determine acceptable values and ranges for the dimension $d = 4$ and $d = 6$ condensates, as well as their correlation.

7.1.1 1-parameter fit: determination of \mathcal{O}_4^A

By a 1-parameter fit we aim to determine the dimension $d = 4$ condensate \mathcal{O}_4^A at leading order. Even though NLO corrections are calculated (see Eq.(7.10)), we will not take them into account. We have learned from similar fits performed in the $V - A$ channel that they are not changing qualitatively the result.

For defining an estimate for the error corridor in the space-like region one can choose to use the last known term of the perturbation series, or the first omitted term in the OPE, or a combination of the two of them:

$$\sigma_L(x) = \begin{cases} \frac{1}{4\pi^2} K_3 \left(\frac{\alpha_s(-x)}{\pi} \right)^3, \\ 3 \frac{\mathcal{O}_6^A}{(-x)^3}, \\ \sqrt{\left[\frac{1}{4\pi^2} K_3 \left(\frac{\alpha_s(-x)}{\pi} \right)^3 \right]^2 + \left[3 \frac{\mathcal{O}_6^A}{(-x)^3} \right]^2}. \end{cases} \quad (7.11)$$

A typical result of the algorithm is shown in Fig.7.1. One can see that the regularised function (Fig. 7.1(b)) follow nicely the data points, except at large s and, as expected, χ_L^2 has the quadratic dependence on \mathcal{O}_4^A .

Figure 7.1: A typical result of the algorithm: (a) χ_L^2 as a function of \mathcal{O}_4^A ; (b) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (c) difference between data and the regularised function. For the error corridor the first omitted term in the OPE was used with $|\mathcal{O}_6^A|_{\max} = 1 \times 10^{-3} \text{GeV}^6$.

We have performed a series of consistency checks summarised in Figs. 7.2, 7.3 and 7.4, i.e., we have studied the behaviour of the algorithm with respect to various

parameters: the number of experimental data points N used in the analysis, the end-points of the time-like interval Γ_L , s_1 and s_2 , as well as the dependence on the error parameter \mathcal{O}_6^A .

Like for the $V - A$ channel, one can show that the information on the condensate is contained in the lower part of the spectrum by adding or removing data-points contained in the saturated upper part of the spectrum: this would not change the result (Fig.7.2 , left panel). However, one can observe that there exists also a region which deviates from the saturated one, for $N \leq 125$. In this region, the high oscillation in data points as well as small experimental errors play an important role. A good argument to remove these data points from the spectrum, i.e., not to use them in the analysis, is to check whether the consistency between theory and data is good enough when including them. This is not the case (see Fig.7.2 , right panel) and thus for the rest of the analysis we will use only the first $N = 120$ data points.

Figure 7.2: \mathcal{O}_4^A (left) and $\chi_{L,\min}^2$ (right) as a function of the first N data points used in the analysis.

Studying the behaviour of the algorithm with respect to changes of s_2 , we found that the best simultaneous description of experimental data and theory is when we choose to define the error corridor with the help of the last known term in the perturbation series, i.e.,

$$\sigma_L(s) = \frac{1}{4\pi^2} K_3 \left(\frac{\alpha_s(-x)}{\pi} \right)^3. \quad (7.12)$$

This is well illustrated in Figs. 7.3 and 7.4, where the dependence of \mathcal{O}_4^A and respectively $\chi_{L,\min}^2$ on s_2 is plotted for all three possible error corridors. Based on these plots we further use the error corridor defined by Eq.(7.12) and quote results for $s_2 = -3.5\text{GeV}^2$.

We have also observed a well-defined plateau for the value of \mathcal{O}_4^A as a function of s_1 between -1.5 and 0GeV^2 and quote the results for $s_1 = -0.4\text{GeV}^2$.

Figure 7.3: \mathcal{O}_4^A as a function of the lower end of the space-like interval Γ_L , s_2 , for the three possible error corridors: (a) error corridor defined by the last known term in the perturbation expansion, (b) error corridor defined by the first omitted contribution in the OPE, (c) error corridor defined by the combination of the two previous cases. For the cases (b) and (c), $|\mathcal{O}_6^A|_{\max} = 3 \times 10^{-3}\text{GeV}^6$.

Figure 7.4: $\chi_{L,\min}^2$ as a function of the lower end of the space-like interval Γ_L , s_2 , for the three possible error corridors: (a) error corridor defined by the last known term in the perturbation expansion, (b) error corridor defined by the first omitted contribution in the OPE, (c) error corridor defined by the combination of the two previous cases. For the cases (b) and (c), $|\mathcal{O}_6^A|_{\max} = 3 \times 10^{-3}\text{GeV}^6$.

Now, the results of the 1-parameter fit at LO can be summarised by quoting the value for \mathcal{O}_4^A :

$$\mathcal{O}_4^A = 2.8_{-0.8}^{+0.6} \times 10^{-3}\text{GeV}^4 \quad \text{at } 66.57\%\text{CL}. \quad (7.13)$$

According to Eq.(7.10) and keeping in mind the chiral symmetry underlying our analysis, i.e., assuming $\mathcal{O}_4^{V-A} = 0$, one can translate the value of \mathcal{O}_4^A into values for the gluon condensate

$$\left\langle \frac{\alpha_s}{\pi} G_{\mu\nu}^a G_{\mu\nu}^a \right\rangle = 3.36_{-0.96}^{+0.72} \times 10^{-2} \text{GeV}^4. \quad (7.14)$$

This result is in good agreement with the first extraction by Shifman, Vainshtein and Zakharov in [SVZ79a].

7.1.2 2-parameter fit: $\mathcal{O}_4^A - \mathcal{O}_6^A$ correlation

A two parameter fit is also possible. We aim to fit the condensates of dimension $d = 4$ and $d = 6$ at leading order. Based on the results from the 1-parameter fit we will take the last known term of the perturbative series as a sensible estimate for the error corridor on the space-like region, Eq.(7.12). All the consistency checks performed for the 1-parameter fit remain valid and thus we keep the corresponding parameters, i.e., s_1 , s_2 and N , at the quoted values (see Section 7.1.1).

The result of the 2-parameter analysis is presented in Fig.7.5. This result corresponds to a 62.58%CL agreement of experimental data with theory. As in the 1-parameter case, a direct comparison of experimental data with the regularised function $f(s)$ (see Figs. 7.5(a) and 7.5(b)) shows a nice agreement over the full range of s with the exception of the highest s -bins. We can then conclude that including the contribution from the next higher-order condensate in the OPE does not improve the quality of the fit.

Also χ_L^2 (Fig.7.5(d)) has the expected quadratic dependence on the two free parameters, \mathcal{O}_4^A and \mathcal{O}_6^A . Fig.7.5(c) shows lines of constant values of χ_L^2 projected on the $(\mathcal{O}_4^A, \mathcal{O}_6^A)$ -plane corresponding to 1-, 2- and 3 σ CR around the two parameters (for a definition of these confidence regions one can consult Appendix D.2). As seen, there exists a strong negative correlation of \mathcal{O}_4^A and \mathcal{O}_6^A , the central values, i.e., the values corresponding to $\chi_{L,\min}^2$, being located at:

$$\begin{aligned} \mathcal{O}_4^A &= 3.8_{-0.9}^{+1.1} \times 10^{-3} \text{GeV}^4, \\ \mathcal{O}_6^A &= -1.0_{-0.7}^{+0.6} \times 10^{-3} \text{GeV}^6. \end{aligned} \quad (7.15)$$

These values are at the same 62.58%CL for the agreement between theory and data. The errors presented are the 1σ errors.

The strong correlation allows one to determine a linear combination of \mathcal{O}_4^A and \mathcal{O}_6^A with rather small errors:

$$\mathcal{O}_6^A + 0.65 \text{GeV}^2 \cdot \mathcal{O}_4^A = 1.60_{-0.25}^{+0.26} \times 10^{-3} \text{GeV}^6, \quad (7.16)$$

and thus if one of the parameters is known from an independent determination, one could specify the value of the other one with well defined errors.

These results are in agreement with those from the 1-parameter fit. However, since here the value of \mathcal{O}_6^A was left unconstrained, we have found a larger range for \mathcal{O}_4^A .

Figure 7.5: *A* analysis, 2-parameter fit (LO) at 62.58%CL for the agreement between theory and data: (a) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (b) difference between data and the regularised function; (c) 1-, 2- and 3σ confidence regions in the $(\mathcal{O}_4^A, \mathcal{O}_6^A)$ -plane; The central values are marked by dashed lines. (d) χ_L^2 [Eq.(5.10)] as a function of \mathcal{O}_4^A and \mathcal{O}_6^A .

7.2 V and $V + A$ analysis

We will now move to the analysis of the V and $V + A$ channels. We will again perform 1- and 2-parameter fits and quote their results.

7.2.1 1-parameter fits

Let us first start with the 1-parameter fits and aim to determine the dimension $d = 4$ condensates \mathcal{O}_4^V and \mathcal{O}_4^{V+A} at leading order. Like for the A channel, since the correlators are dominated by the perturbative regime, there are three possible choices for the error corridor on the space-like region, i.e.,

$$\sigma_L(x) = \begin{cases} \frac{1}{4\pi^2} K_3 \left(\frac{\alpha_s(-x)}{\pi} \right)^3, \\ 3 \frac{\mathcal{O}_6^V}{(-x)^3}, \\ \sqrt{\left[\frac{1}{4\pi^2} K_3 \left(\frac{\alpha_s(-x)}{\pi} \right)^3 \right]^2 + \left[3 \frac{\mathcal{O}_6^V}{(-x)^3} \right]^2}, \end{cases} \quad (7.17)$$

for the V channel. For the $V+A$ channel one needs to add the separate contributions coming from the V , Eq.(7.17), and A , Eq.(7.11), channels. One should keep in mind that $\mathcal{O}_d^{V+A} = \mathcal{O}_d^V + \mathcal{O}_d^A$ for any dimension d .

Figure 7.6: A typical result for the V analysis: (a) χ_L^2 as a function of \mathcal{O}_4^V ; (b) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (c) difference between data and the regularised function. We have chosen for the error parameter $\mathcal{O}_6^V = 1 \times 10^{-3} \text{GeV}^6$.

Figure 7.7: A typical result for the $V + A$ analysis: (a) χ_L^2 as a function of \mathcal{O}_4^{V+A} ; (b) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (c) difference between data and the regularised function. We have chosen for the error parameter $\mathcal{O}_6^{V+A} = 1 \times 10^{-3} \text{GeV}^6$.

Typical results of the algorithm, for both channels, are shown in Figs. 7.6 and 7.7. Again, as we have seen in the analysis of the $V - A$ and A channels, the regularised function follows nicely the data points, except at large s , and χ_L^2 has the expected quadratic dependence.

We have performed all the consistency checks discussed in the analysis of the A channels and found no justification to change the number of data points N used in the analysis or s_1 , the upper limit of the space-like interval Γ_L . Also, the dependence on the lower limit s_2 shows again that the best simultaneous description of theory and data corresponds to an error corridor defined by the last known term in the perturbative series. Unfortunately this agreement is very poor now for the V and $V + A$ channels, the corresponding $\chi_{L,\min}^2$ being in the order of $O(10)$ while a value in the order of $O(1)$ is expected.

The results of these 1-parameter fits are:

$$\mathcal{O}_4^V = 2.6_{-0.9}^{+0.9} \times 10^{-3} \text{GeV}^4 \quad \text{at } 0.28\% \text{CL}, \quad (7.18)$$

$$\mathcal{O}_4^{V+A} = 5.4_{-1.9}^{+1.7} \times 10^{-3} \text{GeV}^4 \quad \text{at } 9.17\% \text{CL}.$$

As before, these values can be translated into values for the gluon condensate:

$$\langle \frac{\alpha_s}{\pi} G_{\mu\nu}^a G_{\mu\nu}^a \rangle = 3.12_{-1.08}^{+1.08} \times 10^{-2} \text{GeV}^4 \quad \text{from the } V \text{ channel}, \quad (7.19)$$

$$\langle \frac{\alpha_s}{\pi} G_{\mu\nu}^a G_{\mu\nu}^a \rangle = 3.24_{-1.14}^{+1.02} \times 10^{-2} \text{GeV}^4 \quad \text{from the } V + A \text{ channel}.$$

Both results, Eqs. 7.18 and 7.19, agree with the corresponding results from the A analysis, Eqs. 7.13 and 7.14, respectively. Even though in the present analysis there is a poor agreement between theory and data, the extracted values for the

condensates seem to be conclusive. As expected, the values of \mathcal{O}_4^A and \mathcal{O}_4^V are almost equal and their sum agrees nicely with the one extracted from the $V + A$ channel.

7.2.2 2-parameter fits

We have also performed 2-parameter fits to determine the correlation between the dimension $d = 4$ and $d = 6$ condensates. For this purpose, we have kept all the other parameters at the quoted values (see consistency checks for the 1-parameter fits) and found the results presented in Figs. 7.8 and 7.9. Even though these results are as expected, i.e., the regularised function $f(s)$ follows nicely the data points and χ_L^2 has a quadratic behaviour, the problem of having $\chi_{L,\min}^2$ in the order $O(10)$ still persists and thus the corresponding CL, taken from Fig.D.3 in Appendix D, is very small.

One can see that also in these two channels one finds a strong correlation between the two parameters with the central values:

$$\begin{aligned} \mathcal{O}_4^V &= 6.1_{-1.1}^{+0.9} \times 10^{-3} \text{GeV}^4, \\ \mathcal{O}_6^V &= -3.3_{-0.6}^{+0.7} \times 10^{-3} \text{GeV}^6, \end{aligned} \quad \text{at } < 0.01\% \text{CL } (\chi_{L,\min}^2 = 20.42), \quad (7.20)$$

$$\begin{aligned} \mathcal{O}_4^{V+A} &= 9.9_{-2.0}^{+2.1} \times 10^{-3} \text{GeV}^4, \\ \mathcal{O}_6^{V+A} &= -4.2_{-1.3}^{+1.3} \times 10^{-3} \text{GeV}^6, \end{aligned} \quad \text{at } 0.08\% \text{CL } (\chi_{L,\min}^2 = 7.11). \quad (7.21)$$

Due to the negative correlation, Figs. 7.8(c) and 7.9(c) contain a lot of information about a specific combination of the two parameters, which allows the determination of one of the parameters, with well defined errors, if the other one is known from an independent analysis. These combinations are:

$$\begin{aligned} \mathcal{O}_6^V + 0.65 \text{GeV}^2 \cdot \mathcal{O}_4^V &= 0.66_{-0.25}^{+0.25} \times 10^{-3} \text{GeV}^6, \\ \mathcal{O}_6^{V+A} + 0.65 \text{GeV}^2 \cdot \mathcal{O}_4^{V+A} &= 2.20_{-0.51}^{+0.50} \times 10^{-3} \text{GeV}^6. \end{aligned} \quad (7.22)$$

Despite the poor agreement of theory with data, present in the analysis of the V and $V + A$ channels, it is important to remark that the values and allowed ranges for the condensates are in good agreement with those found from the A and $V - A$ channels. Note that the slope of the correlations in the V , A and $V + A$ channels is identical, and thus allowing one to see that the sum of the V and A channels agrees with that found in the $V + A$ case. Also the central values agree within errors. For the $V - A$ case, the values for both condensates, of dimension $d = 4$ and $d = 6$, agree with the values found by actually taking the difference between the results from the V and A channels separately.

Figure 7.8: V analysis, 2-parameter fit (LO) at $< 0.01\%$ CL ($\chi_{L,\text{min}}^2 = 20.42$) for the agreement between theory and data: (a) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (b) difference between data and the regularised function; (c) 1-, 2- and 3 σ confidence regions in the $(\mathcal{O}_4^V, \mathcal{O}_6^V)$ -plane; The central values are marked by dashed lines. (d) χ_L^2 [Eq.(5.10)] as a function of \mathcal{O}_4^V and \mathcal{O}_6^V .

Figure 7.9: $V + A$ analysis, 2-parameter fit (LO) at 0.08%CL ($\chi_{L,\text{min}}^2 = 7.11$) for the agreement between theory and data: (a) the regularised function $f(s)$ [Eq.(5.13)] compared with data [ALEPH05]; (b) difference between data and the regularised function; (c) 1-, 2- and 3 σ confidence regions in the $(\mathcal{O}_4^{V+A}, \mathcal{O}_6^{V+A})$ -plane; The central values are marked by dashed lines. (d) χ_L^2 [Eq.(5.10)] as a function of \mathcal{O}_4^{V+A} and \mathcal{O}_6^{V+A} .

7.3 Review and comparison of results

Besides a consistency check of the results presented in this work, one should also compare them to those from other groups. There exist in the literature some previous extractions of QCD condensates in the V and A channels. They are based on sum rules approaches and the analysis is performed at leading order. However, the normalisation of spectral functions is different from ours and there are also other factors absorbed in the definition of the condensates. We have translated the results so that they can be compared to ours. They can be found in Table 7.1.

	V channel		A channel	
	\mathcal{O}_4^V	\mathcal{O}_6^V	\mathcal{O}_4^A	\mathcal{O}_6^A
[Be88]	(1.8 – 4.8)	– (12.9 – 8.4)		
[DS88]	(0.6 – 2.8)	– (8.1 – 4.1)	(1.2 – 2.5)	(4.1 – 7.1)
[DS07]	(1.3 – 4.8)	– (19.0 – 5.9)	(1.3 – 4.8)	– (16.5 – 1.3)

Table 7.1: Estimated ranges for the dimension $d = 4$ and $d = 6$ condensates of the V and A channels in units of 10^{-3}GeV^d at leading order. Existing results from the literature are presented. Note that the normalisation, for all of them, was adjusted so that they can be compared to those from this work.

	V channel		A channel		V + A channel	
	\mathcal{O}_4^V	\mathcal{O}_6^V	\mathcal{O}_4^A	\mathcal{O}_6^A	\mathcal{O}_4^{V+A}	\mathcal{O}_6^{V+A}
1-parameter fit	$2.6_{-0.9}^{+0.9}$		$2.8_{-0.8}^{+0.6}$		$5.4_{-1.9}^{+1.7}$	
2-parameter fit	$6.1_{-1.1}^{+0.9}$	$-3.3_{-0.6}^{+0.7}$	$3.8_{-0.9}^{+1.1}$	$-1.0_{-0.7}^{+0.6}$	$9.9_{-2.0}^{+2.1}$	$-4.2_{-1.3}^{+1.3}$

Table 7.2: Results of this work for the dimension $d = 4$ and $d = 6$ condensates in units of 10^{-3}GeV^d at leading order.

One can remark that the values found in this work (Table 7.2) are consistent with those from the literature. The sign of \mathcal{O}_6^A , though, disagrees with the vacuum saturation approximation, provided \mathcal{O}_6^V is negative, as we have found here. The negative sign of \mathcal{O}_6^A disagrees also with the results from [DS88].

As a conclusion, we can state that the values and ranges found for the QCD condensates are all consistent among themselves and with previous extractions found in the literature even though the agreement between theory and data is very poor in the case of the V and $V + A$ channels. However, one can hope that when eliminating some (or all) of the restrictions imposed when performing the analysis the agreement between theory and data will improve.

When analysing all four channels, we have assumed chiral symmetry, decoupling of heavy quarks and no duality violation. If the chiral symmetry is broken, there are also lower order terms entering the OPE and also mass terms would be present

both in the OPE and the perturbative expansion. As a consequence, there will be also a perturbative contribution to the $V - A$ correlator. These terms could change the results, however remains to be seen if the effect is negligible or not.

Also the inclusion of heavy quarks could change the results. Heavy quarks are expected to play an important role at high energies, i.e., they could play a sensible role for the lower end of the space-like interval, s_2 , as well as for $\Gamma_{\text{exp}} : (s_{\text{max}}, \infty)$ where several resonances are known. For a detailed discussion of these resonances one can look for example in [EJKV99] and the references therein.

Duality refers to the fact that, if the approximation $\Pi(s) \rightarrow \Pi_{\text{OPE}}(s)$ were exact and this substitution carried no error, one can say that the experimental spectral function $\text{Im}\Pi(t)$ is dual to $\Pi_{\text{OPE}}(s)$. The term *duality violation*, consequently, refers to any contribution missed by this substitution.

As stated above, in our analysis we have assumed no duality violation. However it is interesting to check if, and how much, the results would change if one would consider duality violation contributions. Unfortunately, the theory of duality violation in QCD is almost non-existing. Ref.[Sh00] was the first to point out the importance of duality violations. That the OPE may also miss other important contributions has recently been suggested in [Za03]. A model of duality violation can be found in [CGP05].

The inverse conductivity problem

Electrical impedance tomography

Magnetic resonance imaging (MRI), functional MRI (fMRI), X-ray tomography or computed tomography (CT), magnetic encephalography (MEG) and ultrasound imaging are examples of medical imaging methods that produce a picture of a patient's inner organs without intruding into the body. Images coming from different systems complement each other since each of these methods measures the distribution of some specific physical parameter, such as mass density (CT) or sound speed (ultrasound imaging).

Figure 8.1: Electrodes attached on the boundary of an object for current injection and voltage measurement.

Some of the methods are more harmful to the patient than others: X-ray measurements expose her to dangerous radiation whereas ultrasound imaging has little or no health risks. Another difference between the systems is that some of the machines are very expensive. For these reasons it is valuable to have as many different imaging methods available as possible.

Electrical impedance tomography (EIT) is a medical imaging system that produces a picture of the electric conductivity distribution inside the patient. For the EIT measurement an array of electrodes is attached for instance around the chest of the patient. Measurements are done by feeding electric currents through the electrodes and measuring the corresponding voltages at the electrodes. This measurement is repeated with several different choices of current patterns. The resulting image is an approximate map of the electric conductivity.

Electrical properties such as the electrical conductivity σ and the electric susceptibility ϵ , determine the behaviour of materials under the influence of external

electric fields. For example, conductive materials have a high electrical conductivity and both direct and alternating currents flow easily through them. Dielectric materials have a large electric susceptibility and they allow passage of only alternating electric currents.

Figure 8.2: EIT is a nonlinear problem.

The mathematical task of interpreting EIT measurements is an inverse boundary-value problem called the *inverse electric conductivity problem*. It is a challenging question in the theory of partial differential equations since it is nonlinear and ill-posed. Designing a practical algorithm for EIT is hard because non-linearity makes the mathematical solution theoretically difficult and ill-posedness means that a small error in the practical measurements may cause a large error in the reconstructed image.

Let us consider a bounded, simply connected region $\Omega \subset \mathbb{R}^n$, for $n \geq 2$ and, at frequency ω , let γ be the complex admittivity function

$$\gamma(\mathbf{x}, \omega) = \sigma(\mathbf{x}) + i\omega\epsilon(\mathbf{x}), \quad (8.1)$$

where $\sigma(\mathbf{x})$ is called the conductivity and $\epsilon(\mathbf{x})$ the susceptibility.

The electrical impedance is the inverse of $\gamma(\mathbf{x})$ and it measures the ratio between the electric field and the electric current at location $\mathbf{x} \in \Omega$. Electrical impedance tomography is the inverse problem of determining the impedance in the interior of Ω , given simultaneous measurements of direct or alternating electric currents and voltages at the boundary $\partial\Omega$.

Different materials have different electrical properties, as shown in Tables 8.1 and 8.2, so a map of $\sigma(\mathbf{x})$ and $\epsilon(\mathbf{x})$, for $\mathbf{x} \in \Omega$, can be used to infer the internal structure in Ω . Due to this fact, EIT is an imaging tool with important applications in vastly different fields such as medicine, geophysics, environmental sciences and non-destructive testing of materials. Examples of medical applications of EIT are the detection of pulmonary emboli [CIN99, HSBB87, Ho93], monitoring of apnoea [ATW90], monitoring of heart function and blood-flow [CFGTV79, IC90] and breast cancer detection [CIN99]. In geophysics and environmental sciences, EIT can be useful for locating underground mineral deposits [Pa84], detection of leaks in underground storage tanks [RDBLR96] and for monitoring flows of injected fluids into the earth, for the purpose of oil extraction or environmental cleaning [RDBLOC93]. Finally, in non-destructive testing, EIT can be used for the detection of corrosion [SKV96] and of small defects, such as cracks or voids, in metals [ABSV95, AR98, CFMV98, ESIC89, FV89, SV91].

Rock or fluid	$1/\sigma$ (Ω cm)
Marine sand, shale	1-10
Terrestrial sands, claystone	15-50
Volcanic rocks, basalt	10-200
Granite	500-2000
Limestone dolomite, anhydrite	50-5000
Chloride water from oil fields	0.16
Sulfate water from oil fields	1.2

Table 8.1: Resistivity of rocks and fluids [Ke88].

Tissue	$1/\sigma$ (Ω cm)	ϵ (μ Fm $^{-1}$)
Lung	950	0.22
Muscle	760	0.49
Liver	685	0.49
Heart	600	0.88
Fat	>1000	0.18

Table 8.2: Electrical properties of biological tissue measured at frequency 10kHz [BB84, SK57].

EIT has been studied extensively in the last two decades and substantial progress has been made in both the theoretical and applied aspects of the problem. At the same time, EIT remains an area of active research and it continues to pose a variety of challenging questions for theoreticians, numerical analysts and experimentalists alike.

8.1 The mathematical model

Electric and magnetic fields with harmonic time dependence

$$\mathcal{E}(\mathbf{x}, t) = \text{Re}\{\mathbf{E}(\mathbf{x}, \omega)e^{i\omega t}\}, \quad (8.2)$$

$$\mathcal{H}(\mathbf{x}, t) = \text{Re}\{\mathbf{H}(\mathbf{x}, \omega)e^{i\omega t}\},$$

satisfy Maxwell's equations in the following form:

$$\nabla \times \mathbf{H}(\mathbf{x}, \omega) = \gamma(\mathbf{x}, \omega)\mathbf{E}(\mathbf{x}, \omega), \quad (8.3)$$

$$\nabla \times \mathbf{E}(\mathbf{x}, \omega) = -i\omega\mu(\mathbf{x})\mathbf{H}(\mathbf{x}, \omega),$$

where $\mu(\mathbf{x})$ is the magnetic permeability. EIT operates at low frequencies ω , in a regime with admittivities γ and length scales L satisfying $\omega\mu \mid \gamma \mid L^2 \ll 1$, such

that, after a simple scaling analysis [CIN99], equations (8.3) are approximated by

$$\begin{aligned}\nabla \times \mathbf{H}(\mathbf{x}, \omega) &= \gamma(\mathbf{x}, \omega) \mathbf{E}(\mathbf{x}, \omega), \\ \nabla \times \mathbf{E}(\mathbf{x}, \omega) &= 0.\end{aligned}\tag{8.4}$$

We define the scalar electric potential ϕ and the vector-valued, electric current density with harmonic time dependence $\mathcal{I}(\mathbf{x}, t) = \text{Re}\{\mathbf{j}(\mathbf{x}, \omega)e^{i\omega t}\}$, as

$$\mathbf{E}(\mathbf{x}, \omega) = -\nabla\phi(\mathbf{x}, \omega), \quad \nabla \times \mathbf{H}(\mathbf{x}, \omega) = \mathbf{j}(\mathbf{x}, \omega),\tag{8.5}$$

such that the first equation in (8.4) becomes Ohm's law

$$\mathbf{j}(\mathbf{x}) = -\gamma(\mathbf{x}, \omega) \nabla\phi(\mathbf{x}, \omega).\tag{8.6}$$

Note that the density of dissipated energy, averaged over a period of oscillations,

$$\begin{aligned}\frac{\omega}{2\pi} \int_t^{t+\frac{2\pi}{\omega}} \mathcal{I}(\mathbf{x}, \tau) \cdot \mathcal{E}(\mathbf{x}, \tau) d\tau &= \\ &= \frac{1}{2} [\text{Re}\{\mathbf{j}(\mathbf{x}, \omega)\} \cdot \text{Re}\{\mathbf{E}(\mathbf{x}, \omega)\} + \text{Im}\{\mathbf{j}(\mathbf{x}, \omega)\} \cdot \text{Im}\{\mathbf{E}(\mathbf{x}, \omega)\}] \\ &= \frac{1}{2} \sigma(\mathbf{x}) |\nabla\phi(\mathbf{x}, \omega)|^2,\end{aligned}\tag{8.7}$$

must be strictly positive, so we require that

$$\sigma(\mathbf{x}) = \text{Re}\{\gamma(\mathbf{x}, \omega)\} \geq m > 0,\tag{8.8}$$

with m a positive constant.

If there are no electrical sources within Ω , by definition, \mathbf{j} is divergence free so Ohm's law (8.6) gives the partial differential equation

$$\nabla \cdot [\gamma(\mathbf{x}, \omega) \nabla\phi(\mathbf{x}, \omega)] = 0 \quad \text{in } \Omega,\tag{8.9}$$

which one should consider together with either Dirichlet boundary conditions

$$\phi(\mathbf{x}, \omega) = V(\mathbf{x}, \omega), \quad \text{for } \mathbf{x} \in \partial\Omega,\tag{8.10}$$

or Neumann boundary conditions

$$\gamma(\mathbf{x}, \omega) \nabla\phi(\mathbf{x}, \omega) \cdot \mathbf{n}(\mathbf{x}) \equiv \gamma(\mathbf{x}, \omega) \frac{\partial\phi(\mathbf{x}, \omega)}{\partial n} = I(\mathbf{x}, \omega) \quad \text{at } \partial\Omega,\tag{8.11}$$

such that

$$\int_{\partial\Omega} I(\mathbf{x}, \omega) ds(\mathbf{x}) = 0,\tag{8.12}$$

where $\mathbf{n}(\mathbf{x})$ is the outer-pointing normal at $\mathbf{x} \in \partial\Omega$.

The boundary value problems (8.9–8.10) or (8.9–8.11) for a known function $\gamma(\mathbf{x}, \omega)$ in Ω and data $I(\mathbf{x}, \omega)$ or $V(\mathbf{x}, \omega)$, given for all $\mathbf{x} \in \partial\Omega$, are referred to as *continuum, forward* mathematical problems for EIT¹.

¹Analytic and semi-analytic solutions to a number of forward problems related to the image reconstruction problem of EIT in two and three dimensions can be found in [PKL95].

8.2 Modelling the electrodes

In practice, we do not know the boundary current $I(\mathbf{x}, \omega)$ for all $\mathbf{x} \in \partial\Omega$. What we actually know are currents flowing along wires which are attached to N discrete electrodes, which in turn are attached to the boundary $\partial\Omega$ [SCI92]. Then, the question is how to model the electrodes?

The *gap model* approximates the current density by a constant at the surface of each electrode and by zero in the gaps between the electrodes. This model is appealing because of its simplicity but it is not accurate [IC91].

A better choice is the *complete model* proposed in [SCI92]. Suppose that $I_l(\omega)$ is the electric current sent through the wire attached to the l -th electrode. At the surface S_l of this electrode, the normal current density satisfies

$$\int_{S_l} \gamma(\mathbf{x}, \omega) \frac{\partial \phi(\mathbf{x}, \omega)}{\partial n} ds(\mathbf{x}) = I_l(\omega). \quad (8.13)$$

In the gaps between the electrodes, we have

$$\gamma(\mathbf{x}, \omega) \frac{\partial \phi(\mathbf{x}, \omega)}{\partial n} = 0. \quad (8.14)$$

At the contact of S_l with $\partial\Omega$, there is in general (often non-negligible) an electrochemical effect which gives rise to a thin, highly resistive layer. This is taken into account by the surface impedance $z_l(\mathbf{x}, \omega)$ and

$$\phi(\mathbf{x}, \omega) + z_l(\mathbf{x}, \omega) \gamma(\mathbf{x}, \omega) \frac{\partial \phi(\mathbf{x}, \omega)}{\partial n} = V_l(\omega) \quad \text{for } \mathbf{x} \in S_l, \quad l = 1, \dots, N, \quad (8.15)$$

where $V_l(\omega)$ is the measured voltage at the l -th electrode. Finally, due to conservation of charge one has

$$\sum_{l=1}^N I_l(\omega) = 0, \quad (8.16)$$

and by choice of ground,

$$\sum_{l=1}^N V_l(\omega) = 0. \quad (8.17)$$

It is proved in [SCI92] that equations (8.9), (8.13-8.17) have a unique solution and that they predict experimental data relatively well. However, the inverse problem based on this complete model remains essentially unstudied from the theoretical and practical points of view.

In our analysis and the applications we discuss, we will use the approximation that the electrodes are point-like and take the current density to be zero in the gaps between them. Such a model is not as accurate as the complete one, but good enough for our purpose to first find qualitative results. Later on, one can try to implement also more complex models, e.g. gap or complete ones.

8.3 Formulation of the inverse problem

In EIT, the admittivity function $\gamma(\mathbf{x}, \omega)$ is unknown and is to be determined from simultaneous measurements of boundary voltages $V(\mathbf{x}, \omega)$ and current densities $I(\mathbf{x}, \omega)$, respectively. There are two maps, the Dirichlet-to-Neumann and Neumann-to-Dirichlet maps, which relate $V(\mathbf{x}, \omega)$ to $I(\mathbf{x}, \omega)$. These maps depend non-linearly on the unknown $\gamma(\mathbf{x}, \omega)$.

The Dirichlet-to-Neumann map $\Lambda_\gamma : H^{1/2}(\partial\Omega) \rightarrow H^{-1/2}(\partial\Omega)$ is defined as²

$$\Lambda_\gamma V(\mathbf{x}, \omega) = \gamma(\mathbf{x}, \omega) \frac{\partial \phi(\mathbf{x}, \omega)}{\partial n} \quad \text{for } \mathbf{x} \in \partial\Omega, \quad (8.18)$$

where $V(\mathbf{x}, \omega)$ is arbitrary in $H^{1/2}$ and $\phi(\mathbf{x}, \omega)$ solves the forward problem (8.9-8.10). In the static case $\omega = 0$, we have $\gamma(\mathbf{x}, \omega) = \sigma(\mathbf{x})$ and $\Lambda_\gamma = \Lambda_\sigma$.

The mathematical formulation of EIT, as first posed by Calderón [Ca80], is as follows: *Find the admittivity function $\gamma(\mathbf{x}, \omega)$ in $L^\infty(\bar{\Omega})^3$, with a strictly positive real part $\sigma(\mathbf{x})$, given the Dirichlet-to-Neumann map Λ_γ .*

In practice, it is not advisable to work with the Dirichlet-to-Neumann map. Instead, one uses the Neumann-to-Dirichlet map $(\Lambda_\gamma)^{-1}$ which is smooth and therefore better behaved for noisy measurements. Nevertheless, in principle, both maps contain the same information and, usually, the Dirichlet-to-Neumann map is used for convenience.

The Neumann-to-Dirichlet map $(\Lambda_\gamma)^{-1} : \mathfrak{l} \rightarrow H^{1/2}(\partial\Omega)$ is defined on the restricted space of currents

$$\mathfrak{l} = \left\{ I(\mathbf{x}, \omega) \in H^{-1/2}(\partial\Omega) \quad \text{such that} \quad \int_{\partial\Omega} I(\mathbf{x}, \omega) ds(\mathbf{x}) = 0 \right\} \quad (8.19)$$

and, for any $I(\mathbf{x}, \omega) \in \mathfrak{l}$,

$$(\Lambda_\gamma)^{-1} I(\mathbf{x}, \omega) = \phi(\mathbf{x}, \omega) \quad \text{at } \partial\Omega, \quad (8.20)$$

where $\phi(\mathbf{x}, \omega)$ is the solution of the Neumann boundary value problem (8.9,8.11). For $\omega = 0$, we have $(\Lambda_\gamma)^{-1} = (\Lambda_\sigma)^{-1}$. We note that $(\Lambda_\gamma)^{-1}$ is the generalised inverse, as defined in Section 2.1, of Λ_γ .

² $H^{1/2}(\partial\Omega)$ are special Sobolev spaces. $H^{-1/2}(\partial\Omega)$ is the dual of $H^{1/2}(\partial\Omega)$. For more details one can consult for example [GT83].

³ $L^\infty(\bar{\Omega})$ denotes the Banach space of bounded functions on $\bar{\Omega}$ with the norm

$$\|u\|_{L^\infty(\bar{\Omega})} = \text{ess sup}_{\bar{\Omega}} |u|.$$

8.4 Imaging with incomplete, noisy data

Figure 8.3: Illustration of experimental setups for gathering partial data about the Neumann-to-Dirichlet map.

In practice, we do not have full knowledge of the maps $(\Lambda_\gamma)^{-1}$ or Λ_γ . Instead, we have a set of N experiments, where we define an excitation pattern $I_e(\mathbf{x}, \omega) \in \mathbb{I}$ and we measure the resulting voltage $V_e(\mathbf{x}, \omega)$, at discrete locations $\mathbf{x}_p \in \partial\Omega$ of the electrodes, along the boundary.

In Fig.8.3 we illustrate two experimental setups: An excitation current I_e is injected (extracted) at some electrodes and the resulting voltage is measured at all or some of the electrodes. The first setup is typical of medical applications, where one has access to all points of the boundary (i.e. the surface of the body or parts of it). The second setup is typical of geophysics applications, where measurements can be made at the earth's surface or in some boreholes. In any case, we say that we have partial knowledge of the Neumann-to-Dirichlet map and, furthermore, the data V_e are usually contaminated with noise. The practical EIT problem is the following: *Find the admittivity function $\gamma(\mathbf{x}, \omega)$, given a partial, noisy knowledge of $(\Lambda_\gamma)^{-1}$.*

8.5 A brief history of the problem

Research on the inverse conductivity problem has two aspects: a purely mathematical one providing answers to the questions of uniqueness and reconstruction and a practical approach having as its goal algorithms that perform well on physical data.

The theoretically oriented line of research was started by Calderón⁴ [Ca80]. He stated the inverse conductivity problem for the first time (in dimensions $n \geq 2$) and gave first results for conductivities close to a constant. Mathematically his work continued the tradition of Gel'fand, Levitan and Börg [Bö48, GL51].

Once Calderón asked his question, new results started to appear. Kohn and Vogelius showed that for piecewise analytic conductivities the Dirichlet-to-Neumann map uniquely determines the conductivity in dimensions 2 or more ($n \geq 2$) [KV84]. Sylvester and Uhlmann showed in dimensions $n \geq 3$ that if $\partial\Omega \subset \mathcal{C}^\infty$ then Λ_σ

⁴He studied first electrical engineering before changing to mathematics.

uniquely determines $\sigma \in \mathcal{C}^\infty(\bar{\Omega})$ [SU87]⁵.

The first reconstruction method was published by A. Nachman [Na88]; this method is valid in dimensions strictly greater than two ($n \geq 3$).

Meanwhile the case $n = 2$ remained unsolved. Why is the two-dimensional case more difficult than the higher-dimensional ones? A naive argument for this is that in n dimensions the Schwartz kernel of Λ_σ depends on $2(n - 1)$ variables while σ is a function of n variables; this means that there is no over-determinacy in two dimensions and all the data have to be used for reconstruction.

Since the inverse conductivity problem is very complicated mathematically, we can expect the practical EIT imaging task to be difficult. In addition to the non-linearity and ill-posedness of the theoretical problem there are further problems: the Dirichlet-to-Neumann map is not given; instead its inverse operator has to be approximated from noisy current-to-voltage measurements with finite-precision. Furthermore, only a finite number of current patterns can be applied through a finite number of electrodes. This situation places restrictions on the resolution of the images and requires the physical model of the electrode system to be refined. This leads to the notion of *distinguishability* describing the resolution it is possible to obtain in principle with a given system.

With these restrictions, many algorithms have been developed and tested on real data. They fall roughly in three categories:

- Solve the linearised inverse problem. This approach works for conductivities close to constant; examples include back-projection and one-step Newton schemes like NOSER.
- Solve the nonlinear problem by finding iteratively a conductivity distribution that matches the physical measurements best in the least squares sense. These methods require regularisation due to the ill-posedness of the inverse problem.
- Solve the problem directly. The methods of this category are called direct methods as opposed to iterative ones; they aim as well to solve the full nonlinear problem.

Some of these ideas combined with elaborate electrical engineering make it possible to build reasonably working EIT devices. This has been done in several laboratories around the world.

⁵ \mathcal{C}^k is the space of functions having k continuous derivatives with a norm defined as:

$$\|f\|_{\mathcal{C}^k(\Omega)} = \sum_{n=0}^k \sup_{x \in \Omega} |f^{(n)}(x)|.$$

Thus, \mathcal{C}^∞ are infinitely derivable functions with continuous derivatives.

The forward problem

The attention given to the direct problem of EIT is due to the fact that many image reconstruction algorithms are iterative and make many comparisons between the boundary data predicted by an estimate of the internal conductivity and the data that are measured. Also, data produced by solving the direct problem for known conductivities is very useful in checking and studying reconstruction algorithms. In the following we discuss a method for solving the direct problem often used in practice.

For an isotropic conductivity distribution $\sigma(\mathbf{x})$ the potential $\phi(\mathbf{x})$ satisfies the equation (see Section 8.1)

$$\nabla \cdot [\sigma(\mathbf{x})\nabla\phi(\mathbf{x})] = 0, \quad (9.1)$$

where $\sigma(\mathbf{x})$ and $\phi(\mathbf{x})$ are defined in a volume Ω bounded by a closed surface $\partial\Omega$. The forward problem described here can be formulated as: *If the conductivity σ is known in Ω , together with either the potential ϕ or the current $\sigma\partial\phi/\partial n$ on the boundary $\partial\Omega$, find the potential ϕ everywhere inside Ω .*

Eq.(9.1) can be written in the form

$$\Delta\phi(\mathbf{x}) = -Y(\mathbf{x}), \quad (9.2)$$

where

$$Y(\mathbf{x}) = \frac{\nabla\sigma(\mathbf{x})}{\sigma(\mathbf{x})} \cdot \nabla\phi(\mathbf{x}) = \nabla\ln\sigma(\mathbf{x}) \cdot \nabla\phi(\mathbf{x}). \quad (9.3)$$

A simplification occurs if $\sigma(\mathbf{x})$ differs only slightly from a constant conductivity distribution

$$\sigma(\mathbf{x}) = \sigma_0 + \delta\sigma(\mathbf{x}). \quad (9.4)$$

Then a linear approximation can be used in (9.2)

$$\Delta\phi(\mathbf{x}) = \frac{\nabla\delta\sigma(\mathbf{x})}{\sigma_0} \cdot \nabla\phi_0(\mathbf{x}) \quad (9.5)$$

where $\phi_0(\mathbf{x})$ is the solution of (9.1) for a constant conductivity σ_0 , i.e. of Laplace's equation.

An elegant way to solve the differential equation (9.2) is by changing it into an integral equation by means of the appropriate Green's function (how this is actually done see Appendix B). Using the Neumann Green's function one gets:

$$\phi(\mathbf{x}) = \psi(\mathbf{x}) + \int_{\Omega} Y(\mathbf{x}')G_N(\mathbf{x}, \mathbf{x}')d^n x', \quad (9.6)$$

where $\psi(\mathbf{x})$ is a harmonic function constructed from the measured Neumann boundary data:

$$\psi(\mathbf{x}) = \langle \phi \rangle_{\partial\Omega} + \oint_{\partial\Omega} \frac{\partial}{\partial n'} \phi(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}') d^{n-1} x'. \quad (9.7)$$

9.1 Methods based on integral equations

As it was shown in [CPSS00, CPS03], one may use the change of variable $\tau = \sqrt{\sigma}$ to transform Eq.(9.1) into an integral equation for the function $\Psi = \tau\phi$. Indeed, using this change of variable, Eq.(9.1) becomes

$$\Delta\Psi(\mathbf{x}) = -V(\mathbf{x})\Psi(\mathbf{x}), \quad \text{where } V(\mathbf{x}) \equiv -\frac{\Delta\tau(\mathbf{x})}{\tau(\mathbf{x})}, \quad (9.8)$$

and, with the help of Green's theorem (see Appendix B), one finds the desired integral equation:

$$\Psi(\mathbf{x}) = \langle \Psi \rangle_{\partial\Omega} + \oint_{\partial\Omega} \frac{\partial}{\partial n'} \Psi(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}') d^{n-1} x' + \int_{\Omega} V(\mathbf{x}') \Psi(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}') d^n x'. \quad (9.9)$$

Once this equation is solved, the potential $\phi(\mathbf{x})$ can be found anywhere in the domain Ω by a simple division of Ψ by τ .

Another way to solve the forward problem consists of applying the operator $\nabla_{\mathbf{x}}(\ln \sigma(\mathbf{x})) \cdot \nabla_{\mathbf{x}}$ to (9.6) to find

$$Y(\mathbf{x}) = \nabla_{\mathbf{x}}(\ln \sigma(\mathbf{x})) \cdot \nabla_{\mathbf{x}} \psi(\mathbf{x}) + \int_{\Omega} K(\mathbf{x}, \mathbf{x}') Y(\mathbf{x}') d^n \mathbf{x}' \quad (9.10)$$

where $K(\mathbf{x}, \mathbf{x}') = \nabla_{\mathbf{x}}(\ln \sigma(\mathbf{x})) \cdot \nabla_{\mathbf{x}} G_N(\mathbf{x}, \mathbf{x}')$.

This is an integral equation for $Y(\mathbf{x})$, the Laplacian of $\phi(\mathbf{x})$. Once $Y(\mathbf{x})$ is known, one can compute $\phi(\mathbf{x})$ by means of a quadrature using again formula (9.6).

Since $\nabla_{\mathbf{x}} G_N(\mathbf{x}, \mathbf{x}')$ is divergent, $K(\mathbf{x}, \mathbf{x}')$ is not a compact operator, that is, the integral equation is not of Fredholm type (see Appendix A). However, by considering its first iteration, that is:

$$Y(\mathbf{x}) = \nabla_{\mathbf{x}}(\ln \sigma(\mathbf{x})) \cdot \nabla_{\mathbf{x}} \psi(\mathbf{x}) + \int_{\Omega} K(\mathbf{x}, \mathbf{x}') \nabla_{\mathbf{x}'}(\ln \sigma(\mathbf{x}')) \cdot \nabla_{\mathbf{x}'} \psi(\mathbf{x}') d^n \mathbf{x}' + \int_{\Omega} K_2(\mathbf{x}, \mathbf{x}') Y(\mathbf{x}') d^n \mathbf{x}' \quad (9.11)$$

with

$$K_2(\mathbf{x}, \mathbf{x}') = \int_{\Omega} \nabla_{\mathbf{x}}(\ln \sigma(\mathbf{x})) \cdot \nabla_{\mathbf{x}} G_N(\mathbf{x}, \mathbf{y}) \nabla_{\mathbf{y}}(\ln \sigma(\mathbf{y})) \cdot \nabla_{\mathbf{y}} G_N(\mathbf{y}, \mathbf{x}') d^n \mathbf{y}, \quad (9.12)$$

one finds a second kind integral equation with a Hilbert-Schmidt kernel (see Appendix A). A proof of this statement can be found in Ref. [CPS04], where a similar approach for solving the forward problem has been presented. The integral equation (9.11) can now be solved by means of usual numerical procedures for Fredholm equations.

9.2 Finite element method

Another way of solving the direct problem is to use the Finite Element Method (FEM). But one should first transform the partial differential equation into a variational problem. This is simply done by taking the weighted integral on both sides of (9.1)

$$0 = \int_{\Omega} w(\mathbf{x}) \nabla \cdot [\sigma(\mathbf{x}) \nabla \phi(\mathbf{x})] d^n x \quad (9.13)$$

with $w(\mathbf{x})$ any square integrable, once differentiable, continuous function, i.e. $w \in H_{\diamond}^1(\Omega)$. Then, by partial integration, one finds an integral condition for the potential inside Ω

$$0 = - \int_{\Omega} \sigma(\mathbf{x}) \nabla w(\mathbf{x}) \cdot \nabla \phi(\mathbf{x}) d^n x + \oint_{\partial\Omega} \sigma(\mathbf{x}) w(\mathbf{x}) \frac{\partial}{\partial n} \phi(\mathbf{x}) d^{n-1} x. \quad (9.14)$$

It is to be remarked that here the Neumann boundary conditions appear naturally.

In this way, the problem of finding the potential ϕ for a known conductivity is changed: *Find the potential ϕ which, for any function $w \in H_{\diamond}^1(\Omega)$, satisfies the condition:*

$$\int_{\Omega} \sigma(\mathbf{x}) \nabla w(\mathbf{x}) \cdot \nabla \phi(\mathbf{x}) d^n x = \oint_{\partial\Omega} w(\mathbf{x}) \sigma(\mathbf{x}) \frac{\partial}{\partial n} \phi(\mathbf{x}) d^{n-1} x. \quad (9.15)$$

Such a formulation is also called a *weak* formulation. It is *weak* in the sense that the local condition for the potential given by the differential equation is now changed into an integral one which is definitely less demanding.

In order to find a numerical solution of Eq.(9.15), let us rewrite it in the form of a variational problem:

$$a(\phi, w) = l(w), \quad \forall w \quad (9.16)$$

with the bilinear form

$$a(u, v) = \int_{\Omega} \sigma \nabla u \nabla v d^n x, \quad (9.17)$$

and the linear functional

$$l(w) = \oint_{\partial\Omega} f w d^{n-1} x, \quad f = \sigma \frac{\partial u}{\partial n}. \quad (9.18)$$

Choosing $\{\varphi_1, \varphi_2, \dots\}$ as a base in the space of the functions w and postulating the expansion

$$\phi = \sum_k z_k \varphi_k \quad (9.19)$$

for the potential, we find the following system of linear equations to be solved:

$$\sum_k z_k a(\varphi_k, \varphi_i) = l(\varphi_i). \quad (9.20)$$

Figure 9.1: Tent functions for the one-dimensional case.

For the computation of (otherwise time consuming) integrals we use linear finite element spaces [PH92]. It is practical to do so since the bases of these spaces are formed out of linear tent-functions (Fig.9.1) and thus, the integrals differ from zero only for nearest neighbour nodal points or when they are taken over the same index.

$$\int_{\Omega} \varphi_k \varphi_i \, d^n x = 0 \quad \forall |k - i| > 1, \quad (9.21)$$

$$\int_{\Omega} \nabla \varphi_k \nabla \varphi_i \, d^n x = 0 \quad \forall |k - i| > 1. \quad (9.22)$$

The matrix inversion is safe since the matrix is positive-definite. Indeed,

$$\begin{aligned} z^T A z &= \sum_{i,k} z_i A_{ik} z_k \\ &= a \left(\sum_i z_i \varphi_i, \sum_k z_k \varphi_k \right) \\ &= a(u, u) \geq \rho \|u\|^2. \end{aligned}$$

Once the system (9.20) is solved, the direct problem is also solved and thus we have the potential ϕ in the whole domain and we can further use it to check our reconstruction algorithms (see next Chapter).

For numerically solving the forward problem we have used MATLAB [KB00], since the FEM is already implemented, for two-dimensional domains, via a toolbox (PDE-Toolbox). The main steps of this algorithm are described below, while the entire code can be found in [AI07].

Algorithm 2: Algorithm for solving the 2-dimensional forward problem by means of FEM in MATLAB.

Data: Geometry of the problem, boundary conditions, conductivity distribution, desired number of electrodes.

Result: Data files containing the potential and current on the electrodes.

begin

 by means of Eq.(9.19) calculate the potential everywhere inside Ω
 calculate the data on the boundary $\partial\Omega$
 write out data files

end

Reconstruction algorithms

It is well known that the inverse conductivity problem is a highly ill-posed, non-linear inverse problem and that the images produced are very sensitive to errors which can occur in practice. There has been much interest in determining the class of conductivity distributions that can be recovered from the boundary data, as well as in the development of related reconstruction algorithms. The interest in this problem has been generated by both difficult theoretical challenges and by the important medical, geophysical and industrial application of it. Much theoretical work has been related to the approach of Calderón concerning the bijection between the conductivity inside the region and the Neumann-to-Dirichlet operator, which relates the distribution of the injected currents to the boundary values of the induced electrical potential, [Ca80, KV85, Na88, SU88]. The reconstruction procedures that have been proposed include a wide range of iterative methods based on formulating the inverse problem as a nonlinear optimisation problem. These techniques are quite demanding computationally particularly when addressing the three dimensional problem. This difficulty has encouraged the search for reconstruction algorithms which reduce the computational demands either by using some *a priori* information e.g. [BH00, BHV03, CFMV98] or by developing non-iterative procedures. Some of these methods [BH00, BHV03] use a factorisation approach while others are based on reformulating the inverse problem in terms of integral equations [CPSS00, CPS03, CPS04].

10.1 Reconstruction from a single measurement

We will present here a reconstruction algorithm based on reformulating the problem in terms of integral equations. A feature of this method is that many of the calculations involve analytical expressions containing the eigenfunctions of the kernel of these integral equations, the computational part being restricted to the introduction of data, the numerical evaluation of some of the analytic formulæ and the solution of a final integral equation.

However, this method requires the knowledge on the boundary $\partial\Omega$ of the domain Ω not only of the electrical potential ϕ and its normal derivative $\partial\phi/\partial n$, but also of the electrical conductivity σ . In geophysics the conductivity on the surface can be measured by taking small soil samples, while in medical applications this might be achieved using closely spaced electrodes.

The method consists in the approximate determination (in the sense of a generalised solution of inverse problems presented in Section 2.1) of $Y(\mathbf{x})$ (Eq.(9.2))

by a single simultaneous measurement of the potential ϕ and its normal derivative $\partial\phi/\partial n$ on the boundary $\partial\Omega$.

10.1.1 The method

One can use Eq.(9.6) to determine the potential on the boundary

$$\phi(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} = \psi(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} + \int_{\Omega} Y(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}')|_{\mathbf{x}\in\partial\Omega} d^n x' \quad (10.1)$$

with

$$\psi(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} = \langle\phi\rangle_{\partial\Omega} + \oint_{\partial\Omega} \frac{\partial}{\partial n'} \phi(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}')|_{\mathbf{x}\in\partial\Omega} d^{n-1} x'. \quad (10.2)$$

Eq.(10.1) represents a generalised Neumann-to-Dirichlet mapping. If the potential $\phi(\mathbf{x})$ is measured on the boundary together with the current distribution $\sigma(\mathbf{x}) \frac{\partial\phi(\mathbf{x})}{\partial n}$, one can determine $Y(\mathbf{x})$ as a (generalised) solution of the integral equation (10.1). One can rewrite this equation in the form

$$F(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} = \int_{\Omega} Y(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}')|_{\mathbf{x}\in\partial\Omega} d^n x', \quad (10.3)$$

where

$$F(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} = -\langle\phi\rangle_{\partial\Omega} + \phi(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} - \oint_{\partial\Omega} \frac{\partial}{\partial n'} \phi(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}')|_{\mathbf{x}\in\partial\Omega} d^{n-1} x' \quad (10.4)$$

contains the measured input. Typically a given current pattern would be applied to the surface $\partial\Omega$ and the resulting surface potential measured. The integral in (10.4) can be evaluated analytically if the applied current pattern is one of the eigenfunctions of the problem. Equivalently this integral can be viewed as the potential $\phi_0(\mathbf{x})$ on the surface $\partial\Omega$ due to a constant conductivity density

$$\phi_0(\mathbf{x})|_{\mathbf{x}\in\partial\Omega} = \oint_{\partial\Omega} \frac{\partial}{\partial n'} \phi(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}')|_{\mathbf{x}\in\partial\Omega} d^{n-1} x' \quad (10.5)$$

The data $F(\mathbf{x})|_{\mathbf{x}\in\partial\Omega}$ are defined on a $(n-1)$ -dimensional manifold $\partial\Omega$, while the unknown functions $Y(\mathbf{x})$ live in the n -dimensional world Ω . As is usual in inverse problems, we seek only a generalised solution of (10.3), i.e., a function $Y(\mathbf{x})$ which under the mapping of (10.3) produces an $F(\mathbf{x})|_{\mathbf{x}\in\partial\Omega}$ that is closest, in a least-squares sense, to the data input and has minimum norm. We rewrite (10.3) in the form

$$F = \mathbf{K}Y, \quad (10.6)$$

with \mathbf{K} an integral operator. Its domain is the whole region Ω and its range the boundary $\partial\Omega$. If the operator \mathbf{K} possesses a singular value decomposition (see Appendix C)

$$\mathbf{K}Y = \sum_{j=1}^{\infty} \sigma_j(Y, v_j) u_j, \quad (10.7)$$

where $\{v_j\}$ is a complete set of basis functions on Ω , $\{u_j\}$ a complete set of basis functions on $\partial\Omega$ and σ_j are the singular values of \mathbf{K} , the least-squares solution of (10.6) will be

$$Y^+ = \sum_{j=1}^{\infty} \frac{1}{\sigma_j} (F, u_j) v_j. \quad (10.8)$$

Due to ill-posedness, one needs to regularise the solution. A convenient tool to carry out this operation is the so called truncated singular value decomposition (Section 2.3). The regularised solution will then be

$$Y_{\text{reg}} = \sum_{j=1}^J \frac{1}{\sigma_j} (F, u_j) v_j. \quad (10.9)$$

Once $Y_{\text{reg}}(\mathbf{x})$ is known, the potential $\phi_{\text{reg}}(\mathbf{x})$ can be obtained by means of the integral

$$\phi_{\text{reg}}(\mathbf{x}) = \psi(\mathbf{x}) + \int_{\Omega} Y_{\text{reg}}(\mathbf{x}') G_N(\mathbf{x}, \mathbf{x}') d^n x'. \quad (10.10)$$

To determine the regularised conductivity $\sigma_{\text{reg}}(\mathbf{x})$, one can use the method of characteristics to solve the first order partial differential equation (see Eq.(9.3)):

$$\nabla(\ln \sigma_{\text{reg}}(\mathbf{x})) \cdot \nabla \phi_{\text{reg}}(\mathbf{x}) - Y_{\text{reg}}(\mathbf{x}) = 0, \quad \mathbf{x} \in \Omega \quad (10.11)$$

subject to the known boundary values $\sigma(\mathbf{x})|_{\mathbf{x} \in \partial\Omega}$.

10.1.2 An example: the unit disc

For the unit disc, Eq.(10.3) takes the form

$$F(\theta) = \int_{\Omega} d^2 x' K(\theta; \mathbf{x}') Y(\mathbf{x}'), \quad (10.12)$$

where

$$F(\theta) = -\langle \phi \rangle_{\partial\Omega} + \phi(r, \theta)|_{r=R} - \int_0^{2\pi} \frac{\partial}{\partial r'} \phi(r', \theta')|_{r'=1} G_N(1, \theta; 1, \theta') d\theta', \quad (10.13)$$

and

$$K(\theta, \mathbf{x}') = \sum_{l,m=1}^{\infty} \sum_{j=1}^2 \sigma_{lm} u_l^j(\theta) v_{lm}^j(r', \theta'), \quad (10.14)$$

with

$$\sigma_{lm} = \frac{1}{\lambda_{lm}} c_{lm} J_l(j_{lm}^*). \quad (10.15)$$

The determination of the eigenvalue expansion for the kernel of Eq.(10.12), can be found in Appendix B.3.

Eq.(10.14) represents the singular value decomposition of the integral operator (Appendix C). The singular functions $\{u_l^j(\theta)\}$ form an orthonormal basis on the unit circle (the range of K) and the singular functions $\{v_{lm}^j(r, \theta)\}$ one on the unit disc (the domain of K) (see Appendix B). The singular values σ_{lm} vanish for large m, l which shows the ill-posedness of the problem (a proof of this statement can be found in Appendix A.3). The least-squares solution of (10.12) reads

$$Y^+(r, \theta) = \sum_{l,m=1}^{\infty} \sum_{j=1}^2 \frac{1}{\sigma_{lm}} \left(\oint_{\partial\Omega} d\theta' F(\theta') u_l^j(\theta') \right) v_{lm}^j(r, \theta). \quad (10.16)$$

An easy way to compute the integrals over the function $F(\theta')$ is to take advantage of the eigenfunction expansion of the Green's function, which on the boundary reads (see Appendix B):

$$G_N(1, \theta; 1, \theta') = \sum_{l=1}^{\infty} \sum_{j=1}^2 \frac{1}{l} u_l^j(\theta) u_l^j(\theta'), \quad (10.17)$$

and write for the data function

$$F(\theta) = -\langle \phi \rangle_{\partial\Omega} + \phi(r, \theta)|_{r=1} - \sum_{l=1}^{\infty} \sum_{j=1}^2 \frac{1}{l} u_l^j(\theta) \int_0^{2\pi} \frac{\partial\phi(r', \theta')}{\partial r'} \Big|_{r'=1} u_l^j(\theta') d\theta'. \quad (10.18)$$

The integration in (10.16) is now straightforward:

$$\int_0^{2\pi} d\theta' F(\theta') u_l^j(\theta') = \phi_l^j - \frac{1}{l} I_l^j, \quad (10.19)$$

where we have introduced the abbreviations:

$$\phi_l^j = \int_0^{2\pi} d\theta \phi(r, \theta)|_{r=1} u_l^j(\theta), \quad (10.20)$$

$$I_l^j = \int_0^{2\pi} d\theta \frac{\partial\phi(r, \theta)}{\partial r} \Big|_{r=1} u_l^j(\theta). \quad (10.21)$$

Thus, the least-squares solution of (10.12) will be:

$$Y^+(r, \theta) = \sum_{l,m=1}^{\infty} \sum_{j=1}^2 \frac{1}{\sigma_{lm}} \left(\phi_l^j - \frac{1}{l} I_l^j \right) v_{lm}^j(r, \theta). \quad (10.22)$$

Performing the regularisation, the final result takes the form:

$$Y_{\text{reg}}(r, \theta) = \sum_{l=1}^L \sum_{m=1}^M \sum_{j=1}^2 \frac{1}{\sigma_{lm}} \left(\phi_l^j - \frac{1}{l} I_l^j \right) v_{lm}^j(r, \theta). \quad (10.23)$$

An algorithm where we have implemented all these steps was written in MATLAB and can be found in [AI07].

10.1.3 Numerical results

To illustrate the performance of such an algorithm, we present here a numerical example. We try to reconstruct a conductivity distribution consisting of a high/low conductivity region within a uniform background. An analytical form of such a conductivity can be chosen as:

$$\sigma(x, y) = 1 + a \exp[b((x - \bar{x})^2 + (y - \bar{y})^2)], \quad (10.24)$$

having a maximum, for $a > 0$, or a minimum, for $a < 0$, at $(x, y) = (\bar{x}, \bar{y})$. In our numerical simulations we have chosen two sets of parameters (a, b, \bar{x}, \bar{y}) : σ_1 with $(1, -1500, 0, 0.4)$ and σ_2 with $(-0.5, -1000, 0.5, 0)$. The two exact conductivities are displayed in the figure below.

Figure 10.1: Density-plot of the two model conductivities considered (see text).

First, one needs to solve the forward problem as in Chapter 9. Let us consider the currents

$$\sigma(r, \theta) \frac{\partial \phi}{\partial n}(r, \theta) \Big|_{\partial \Omega} = \begin{cases} \sin(m\theta) \\ \cos(m\theta) \end{cases}, \quad m \in \mathbb{N}_+ \quad (10.25)$$

as input and simulate the measured values of the potential on the boundary. With the simulated data we can easily compute the coefficients ϕ_i^j and I_i^j needed for the regularised solution $Y_{\text{reg}}(r, \theta)$. To fix the regularisation parameters, i.e., the two summation limits L, M in Eq.(10.23), the interactive method was used and we quote results for the values $L = 10$ and $M = 2$.

$Y_{\text{reg}}(\mathbf{x})$ can already be used directly to obtain rough information on the conductivity. One can observe in Fig.10.2 how the effect of the high/low conductivity region can be observed on the boundary. The angular information is fine but unfortunately there is no radial information present.

It is still interesting to check whether one can get a better picture when including the next step in the reconstruction algorithm, i.e., computing the regularised

potential:

$$\phi_{\text{reg}}(r, \theta) = \psi(r, \theta) + \sum_{k=1}^N w_k G_N(r, \theta; r_k, \theta_k) Y_{\text{reg}}(r_k, \theta_k), \quad (10.26)$$

where $\{w_k; r_k, \theta_k\}$ is a set of N quadrature weights and points for the unit disc [En80], and:

$$\psi(r, \theta) = \langle \phi \rangle_{\partial\Omega} - \frac{1}{2\pi} \int_0^{2\pi} \ln(1 + r^2 - 2r \cos(\theta - \theta')) \left. \frac{\partial \phi}{\partial r'} \right|_{r'=1} d\theta'. \quad (10.27)$$

The actual number of quadrature weights and points used in the reconstruction was $N = 172$.

Figure 10.2: Reconstructed $Y_{\text{reg}}(\mathbf{x})$ for input current $\sin(\theta)$ [Eq.(10.25)]. Reconstructions for the two model conductivities from Fig.10.1 are shown.

Figure 10.3: Reconstructed $\phi_{\text{reg}}(\mathbf{x})$ for input current $\sin(\theta)$ [Eq.(10.25)]. Reconstructions for the two model conductivities from Fig.10.1 are shown.

The reconstructed potential is shown in Fig.10.3. One can conclude that there is no improvement, even worse, in the reconstruction. We believe that by going further and performing also the last step we will not gain more.

Apart from the unsatisfactory reconstruction presented above, the treatment of the inverse conductivity problem with a single set of measurements on two dimensional domains is from practical reasons not advisable. In this case, the information one can use to reconstruct the conductivity is a single set of potentials and currents on the boundary of the domain. For an ideal case this information would be of infinite order, i.e., the potentials and currents would be known at any point of the boundary, but in practice one knows only a finite number of values, corresponding to the number of electrodes. In our numerical example we have used 32 electrodes (to be in accord with practice), so that a good quality of the reconstruction was, in the first place, not to be expected. Besides these practical reasons, the reconstruction algorithm has also a mathematical drawback. In Eq.(10.3) the radial part is integrated out, i.e., we lose any radial information which might be present in K . Eq.(10.3) maps the domain to the boundary, that is it describes a mapping from n to $(n - 1)$ dimensions. The reconstruction algorithm needs then to make the inverse transition, from $(n - 1)$ to n dimensions, which is in principle impossible without additional information, like a model.

Even though the radial information is lost, the angular information present in Y_{reg} can be further used as a qualitative model for similar reconstructions, where this *a priori* information is taken into account. Such an algorithm can be found for example in [CPS04].

10.2 Reconstruction from more measurements

The linearisation of the problem allows us to use the information from more than one single set of measurements for the reconstruction of the conductivity distribution. Using as input more and different current configurations one gets a system of integral equations which can be easily solved by means of the generalised inverse (see Section 2.1). Once the regularisation parameter is fixed, the conductivity distribution is reconstructed by simple matrix multiplication. One needs to perform the matrix inversion only once since the measured data are not contained in the matrix.

10.2.1 Reconstruction by linearisation

Reconstruction of $\delta\sigma$

The starting point for the reconstruction of $\delta\sigma$ is the basic equation of EIT (cf. Eq.(9.1))

$$\nabla \cdot [\sigma(\mathbf{x}) \nabla \phi(\mathbf{x})] = 0. \quad (10.28)$$

In the linear approximation, i.e. when the conductivity distribution differs only slightly from a constant

$$\sigma(\mathbf{x}) = \sigma_0 + \delta\sigma(\mathbf{x}), \quad (10.29)$$

one will have for the potential

$$\phi(\mathbf{x}) = \phi_0(\mathbf{x}) + \delta\phi(\mathbf{x}), \quad (10.30)$$

with $\phi_0(\mathbf{x})$ the solution of (10.28) for the constant conductivity σ_0 . Inserting (10.29) and (10.30) into (10.28) one finds:

$$\nabla [\sigma_0 \nabla \delta\phi(\mathbf{x})] = -\nabla [\delta\sigma(\mathbf{x}) \nabla \phi_0(\mathbf{x})]. \quad (10.31)$$

The Neumann boundary condition of the problem was already considered when computing $\phi_0(\mathbf{x})$ (see Eq.(10.5)), so that one needs to solve (10.31) together with $\partial(\sigma_0 \delta\phi)/\partial n = 0$. Considering $\sigma_0 = 1$, the solution will be:

$$\delta\phi(\mathbf{x}) = \int_{\Omega} G_N(\mathbf{x}, \mathbf{x}') \nabla [\delta\sigma(\mathbf{x}') \nabla \phi_0(\mathbf{x}')] d^n x'. \quad (10.32)$$

The integrand of Eq.(10.32) can be rewritten as

$$\begin{aligned} G_N(\mathbf{x}, \mathbf{x}') \nabla [\delta\sigma(\mathbf{x}') \nabla \phi_0(\mathbf{x}')] &= \nabla [G_N(\mathbf{x}, \mathbf{x}') \delta\sigma(\mathbf{x}') \nabla \phi_0(\mathbf{x}')] \\ &\quad - \nabla G_N(\mathbf{x}, \mathbf{x}') \delta\sigma(\mathbf{x}') \nabla \phi_0(\mathbf{x}'). \end{aligned} \quad (10.33)$$

Taking $\delta\sigma$ to vanish on the boundary, the first term in (10.33) can be omitted, since it appears as a surface term in (10.32). The solution will then become:

$$\delta\phi(\mathbf{x}) = - \int_{\Omega} \nabla G_N(\mathbf{x}, \mathbf{x}') \nabla \phi_0(\mathbf{x}') \delta\sigma(\mathbf{x}') d^n x'. \quad (10.34)$$

Multiplying both sides with the boundary eigenfunctions, u_i , of $G_N(\mathbf{x}, \mathbf{x}')$ and integrating on the boundary, one obtains an integral equation for $\delta\sigma$:

$$\langle \delta\phi, u_i \rangle_{\partial\Omega} = - \int_{\Omega} \nabla \phi_0^i(\mathbf{x}) \nabla \phi_0(\mathbf{x}) \delta\sigma(\mathbf{x}) d^n x. \quad (10.35)$$

Reconstruction of $\ln \sigma$

Alternatively, the first iteration of integral equation (9.6) can be used, i.e.,

$$\phi(\mathbf{x}) = \phi_0(\mathbf{x}) + \int_{\Omega} G_N(\mathbf{x}, \mathbf{x}') \nabla \phi_0(\mathbf{x}') \nabla \ln \sigma(\mathbf{x}') d^n x'. \quad (10.36)$$

Here, the ground was chosen such that $\langle \phi \rangle_{\partial\Omega} = 0$. As before, one can transform the integrand and, assuming $\ln \sigma$ vanishes on the boundary, Eq.(10.36) becomes:

$$\delta\phi(\mathbf{x}) = \phi(\mathbf{x}) - \phi_0(\mathbf{x}) = - \int_{\Omega} \nabla G_N(\mathbf{x}, \mathbf{x}') \nabla \phi_0(\mathbf{x}') \ln \sigma(\mathbf{x}') d^n x'. \quad (10.37)$$

Note that here no linearisation of the conductivity was performed.

Taking the scalar product of $\delta\phi$ with the boundary eigenfunctions of Neumann Green's function, u_i , one finds an integral equation for $\ln \sigma$ similar to (10.35)

$$\langle \delta\phi, u_i \rangle_{\partial\Omega} = - \int_{\Omega} \nabla \phi_0^i(\mathbf{x}) \nabla \phi_0(\mathbf{x}) \ln \sigma(\mathbf{x}) d^n x. \quad (10.38)$$

Comparison: $\delta\sigma$ versus $\ln\sigma$

The kernels of the two integral equations (10.35) and (10.38) are the same, so the quantities to be reconstructed will contain the same information. Indeed, in the linear approximation one has:

$$\ln\sigma(\mathbf{x}) = \ln(1 + \delta\sigma(\mathbf{x})) \approx \delta\sigma(\mathbf{x}). \quad (10.39)$$

However, the reconstruction of $\ln\sigma$ is preferred since in this way the positivity of the reconstructed conductivity distribution is assured.

Discretisation

One can perform a discretisation of (10.38) and of the domain Ω :

$$\langle \delta\phi, u_i \rangle_{\partial\Omega} = - \sum_{k=1}^{N_p} \nabla\phi_0^i(\mathbf{x}_k) \nabla\phi_0(\mathbf{x}_k) \ln\sigma(\mathbf{x}_k) \delta V(\mathbf{x}_k), \quad (10.40)$$

where N_p is number of discretisation points \mathbf{x}_k . For N_m sets of measured data, $\delta\phi_j$, and for N_t “test functions” u_i , one finds the system of equations:

$$\delta\phi_{ij} = \sum_k^{N_p} K_{ijk} \ln\sigma_k \quad (10.41)$$

with the short-hand notations

$$\begin{aligned} \delta\phi_{ij} &= \langle \delta\phi_j, u_i \rangle_{\partial\Omega}, \\ K_{ijk} &= -\nabla\phi_0^i(\mathbf{x}_k) \nabla\phi_0(\mathbf{x}_k) \delta V(\mathbf{x}_k), \\ \ln\sigma_k &= \ln\sigma(\mathbf{x}_k). \end{aligned} \quad (10.42)$$

The matrix inversion will be performed by means of the generalised inverse (see Section 2.1) and the truncated singular value decomposition used as a regularisation scheme. In this way, very small singular values will be cut out and will not enter in the reconstruction. This is a rather obvious choice since the measurement errors are reinforced by small singular values. The regularisation parameter λ , also called cut-off parameter, will be chosen in such a way that the errors are not reinforced but still the reconstruction is close to the true one.

For numerically solving Eq.(10.38), a MATLAB code was written. The important steps of this code are summarised below. The entire code can be found in [AI07].

Algorithm 3: Algorithm for reconstructing the conductivity distribution from more than one set of measurements.

Data: Geometry and data files.

Result: Reconstructed conductivity distribution.

begin

 compute $\delta\phi$ [Eq.(10.42)]

 compute K [Eq.(10.42)]

repeat

 choose λ

 compute the generalised inverse of $K \Rightarrow K^+$

 calculate $\ln \sigma = K^+ \delta\phi$

 calculate $\sigma = \exp(\ln \sigma)$

until $|\sigma - \sigma_{\text{exact}}| < \varepsilon$, ε small

end

10.2.2 Numerical results

As in Section 10.1.2, we have performed tests for our algorithm on a two-dimensional domain, the unit disc. For this specific case, the kernel of the integral equations (10.35) and (10.38) becomes:

$$K_{ij}(r, \theta) = \frac{r^{|i|+|j|-2}}{\pi} \begin{cases} \cos((|i| - |j|)\theta), & i, j > 0 \text{ or } i, j < 0, \\ \sin((|i| - |j|)\theta), & i > 0, j < 0, |j| \geq |i|, \\ \sin((|j| - |i|)\theta), & i < 0, j > 0, |j| \geq |i|. \end{cases} \quad (10.43)$$

The “test functions” are (see Appendix B):

$$u_i(\theta) = \frac{1}{\sqrt{\pi}} \begin{cases} \sin(|i|\theta), & i > 0, \\ \cos(|i|\theta), & i < 0, \end{cases} \quad (10.44)$$

and the potential due to the constant conductivity σ_0 and boundary condition u_i :

$$\phi_0^i(r, \theta) = \frac{r^{|i|}}{|i|} u_i(\theta). \quad (10.45)$$

For the tests we have used several conductivity distributions similar to (10.24):

$$\begin{aligned} \sigma_1(\mathbf{x}) &= 1 + \delta\sigma_1(\mathbf{x}), \\ \sigma_2(\mathbf{x}) &= 1 + \delta\sigma_1(\mathbf{x}) + \delta\sigma_2(\mathbf{x}), \\ \sigma_3(\mathbf{x}) &= 1 + \delta\sigma_1(\mathbf{x}) + \delta\sigma_2(\mathbf{x}) + \delta\sigma_3(\mathbf{x}), \end{aligned} \quad (10.46)$$

with

$$\begin{aligned}\delta\sigma_1(\mathbf{x}) &= \exp \left[-1500 (x^2 + (y - 0.4)^2)^2 \right], \\ \delta\sigma_2(\mathbf{x}) &= -0.5 \exp \left[-2500 ((x - 0.5)^2 + (y + 0.2)^2)^2 \right], \\ \delta\sigma_3(\mathbf{x}) &= 2 \exp \left[-1000 ((x + 0.3)^2 + (y + 0.2)^2)^2 \right].\end{aligned}\tag{10.47}$$

The forward problem has been solved by means of the finite element method described in Section 9.2. The simulated data, i.e. the potential on the boundary, contain no further errors, being exact up to computer accuracy. A first test was performed using the “exact” potential and later, additional errors were added to check the stability of the reconstruction. For the potential ϕ_0 due to a constant conductivity, Eq.(10.5), the theoretically calculated one was used. For the reconstruction, the first 10 input currents were used, that is $m = 1, 2, \dots, 10$ in Eq.(10.25), and both sinus and cosine were considered. The number of electrodes was set to 32.

Figure 10.4: In the upper part, two- and three-dimensional plots of the model conductivity σ_1 , Eq.(10.46), are displayed. The corresponding reconstructed conductivity distribution is shown in the lower part. The regularisation parameter was chosen to be $\lambda = 10^{-6}$.

Figure 10.5: In the upper part, two- and three-dimensional plots of the model conductivity σ_2 , Eq.(10.46), are displayed. The corresponding reconstructed conductivity distribution is shown in the lower part. The regularisation parameter was chosen to be $\lambda = 10^{-6}$.

Figure 10.6: In the upper part, two- and three-dimensional plots of the model conductivity σ_3 , Eq.(10.46), are displayed. The corresponding reconstructed conductivity distribution is shown in the lower part. The regularisation parameter was chosen to be $\lambda = 10^{-6}$.

Figure 10.7: Reconstructed conductivity distribution σ_1 for several values of the regularisation parameter λ .

Figure 10.8: Reconstructed conductivity distribution σ_3 from error affected data: 5% errors (upper part) and 10% errors (lower part).

Figs. 10.4, 10.5 , and 10.6 show the three test conductivity distributions from Eq.(10.46) and their reconstruction. One can see that the positions of the perturbations, as well as their height, are relatively well reconstructed. However, since small singular values are cut-off, i.e., there is some information missing, one cannot reconstruct neither of them exactly. The reconstruction is stable for a well-defined interval of the regularisation parameter, $\lambda \in [10^{-7}, 10^{-4}]$, as depicted in Fig.10.7. There exists no rigorous mathematical reasoning for defining this interval, but one can find it by looking at the changes in the reconstructed conductivity distribution when scanning λ . It is obvious that for too small or too large values, the reconstruction will become very bad. This is the case since for too small values of λ the errors on the data will be reinforced, while for too large values the actual signal gets suppressed.

To check further the stability of our method, we have also added additional randomly distributed errors on the data. This is realistic since in practice the measurements are always accompanied by errors. For big errors the algorithm loses its stability, i.e. the conductivity distribution will be not so well reconstructed. Indeed, one can observe in Fig.10.8, lower part, that the reconstructed perturbations become flatter as compared to the error free data (Fig.10.6) or to the one where the errors on the data are smaller (Fig10.8, upper part). Also, the position of these perturbations is imprecisely reconstructed. These changes are due to the fact that the regularisation parameter needs to be increased, i.e., one has to cut more singular values as in the case of error free data, and hence loose more information.

Reconstructions based on real data

One medical problem for which knowledge of internal electrical properties would be useful is the detection of pulmonary emboli, or blood clots in the lungs. The development of pulmonary emboli is a common, and often serious, complication of surgery. Unfortunately, at present the diagnosis is rather involved, one possibility being the inhalation of radioactive gas in order to determine the ventilated lung region. This is followed by injection of a radio-opaque dye or a dissolved radioactive substance into a vein to make an image of the blood circulation. The image of the circulation in the lungs is compared with the image of the ventilated region; areas that are ventilated but not perfused by blood indicate the presence of emboli.

Another way to determine the location of gas and blood within the body would be to map the internal electric conductivity and susceptibility. These electrical properties are very different for air, tissue, and blood (see Table 8.2, Chapter 8); moreover, they vary on different time scales. Thus a time-varying map of the electrical properties should show lung regions that are ventilated but not perfused by blood.

Furthermore, determining the presence of pulmonary emboli from a map of the electrical properties would have a number of advantages over present techniques. It would require no exposure to X-rays or radioactive material. It would be done at the bedside, with a relatively small and inexpensive electrical system.

Information about the internal electrical properties of a body could have many other medical uses. Such information could potentially be used for the following: monitoring for lung problems such as accumulating fluid or a collapsed lung, noninvasive monitoring of heart function and blood flow, monitoring for internal bleeding, screening for breast cancer, studying emptying of the stomach, studying pelvic fluid accumulation as a possible cause of pelvic pain, quantifying severity of premenstrual syndrome by determining the amount of intracellular vs. extracellular fluid, determining the boundary between dead and living tissue, measuring local internal temperature increases associated with hyperthermia treatments, and improving electrocardiograms and electroencephalograms.

To map the electric conductivity inside a body, a tomograph was constructed in collaboration with Dr. K.H. Georgi and N. Schuster. The electrical measurements were used to reconstruct and display approximate pictures of the electric conductivity inside the body, based on the reconstruction algorithm described in Section 10.2.

11.1 The tomograph

The tomograph consists of three parts: a sensing head, an electronic device to apply and measure electric potential and current patterns, and a computer for the image reconstruction (Fig.11.1). It was designed for mammography applications. For a description of this tomograph we will follow Ref.[AHOS07]. More details can be found in [Az06].

Figure 11.1: The tomograph.

The sensing head has a diameter of 10 cm and consists of 16 large electrodes, arranged on the outer ring of a disk. Through these electrodes the current is injected and both current and voltages can be measured. There is another set of 64 small high-impedance electrodes placed in the interior which can be used to measure additional voltages, however, these measurements have not yet been used to solve the inverse problem.

Figure 11.2: The sensing head.

The data acquisition device consists of five modules. The first module is a micro-controller to facilitate the communication between the measuring device and external components via a RS232 serial interface. The second module generates sinusoidal voltages of frequencies in the range of 5-50KHz which can be used to drive 16 (or 32) current injecting electrodes. The amplitudes can be set positive or negative by 32 DACs to 16-bit accuracy and can be modulated to any desired amplitude pattern. The resulting current at each injection electrode passes through a precision resistor and a special operational amplifier to facilitate the simultaneous measurement of the current. The voltages on the interior electrodes are measured with 16-bit accuracy with the help of the third module. The fourth module serves to read the data and to measure the signal by a peak detector via 8 multiplexers of 16 channels each. The measured value of the peak detector is subsequently digitalised to 16-bit accuracy. In the fifth module, finally, the sign of the modulation is defined. A more detailed description of these five modules is found in [Az06].

There are $N - 1$ independent measurements for N current injecting electrodes. In most reconstruction algorithms it is assumed that currents are prescribed and voltages are measured. Because of the much simpler electronic implementation, voltages are applied and currents are measured on the injectors (voltages are also measured in the interior) in our device. It is, however, no problem to convert to current-driven data by linear combination of the various voltage-driven data. The current-driven data is preferred since, as stated in Section 8.3, the Neumann-to-Dirichlet map (Eq.(8.20)) is better behaved than the Dirichlet-to-Neumann one (Eq.(8.18)) for noisy measurements. For optimal resolution it is of advantage to apply trigonometric voltage or current patterns of different frequencies [HG188].

11.2 Measurements in a test tank

So far we have no clinical data at our disposal. Instead, we have placed the sensing head into the bottom of an appropriate container of large lateral dimensions and filled with a conducting liquid. The level of the liquid in the tank has been kept very low so as to approximate a two-dimensional situation. Various objects have been immersed into the liquid. Measurements have been taken with and without the immersed bodies. The latter serve as reference measurements where necessary.

Fig.11.3 shows such a phantom and the resulting reconstruction [AHOS07]. A metal object of roughly 12×13 mm had been immersed into the tank. The right-hand reconstruction has been computed from a measured reference potential ϕ_0 corresponding to a tank with no object immersed. The one on the left has been computed to simulate a situation where only “absolute” data, i.e., the potentials ϕ are available. Here $\delta\phi$ has been approximated by eliminating the frequency of the injected current from the Fourier spectrum of ϕ . Both reconstructions are fairly good, although the one with “absolute” data is only qualitatively correct. Note that potentials and currents are only known on the 16 planar electrodes that are clearly visible in the photo of the phantom.

Figure 11.3: The phantom and its reconstruction. The reconstruction on the left is from “absolute” data, i.e., no measured reference potential available, while the one on the right is the reconstruction from so called “difference” data, i.e., the measured reference potential was used.

Figure 11.4: Singular values of the matrix (10.42), displayed by the '+' symbols, and the corresponding singular components of the l.h.s. of (10.41), displayed by the 'o' symbols, for the set of data used in the above reconstruction.

For the regularisation, the truncated SVD was implemented. To choose a value for the cut-off parameter λ the interactive method can be used since we exactly know what we want to reconstruct. However, in medical applications one does not have, in general, a picture of the expected conductivity distribution. For this reason we have tried to develop a more mathematically rigorous way to fix λ . The form of the general solution to inverse problems (cf. Eq.(2.14)),

$$f^+ = \sum_{j=1}^{\infty} \frac{1}{\sigma_j} (g, u_j)_Y v_j, \quad (11.1)$$

suggests that one should compare the singular values σ_j with the singular components $(g, u_j)_Y$. As long as the singular values are larger than the singular components, the errors contained in g (data errors) will be suppressed and when the singular values become smaller, the errors will be reinforced. This behaviour is a hint to choose the cut-off parameter in such a way that the singular values and singular components balance each other. In practice, this is done by plotting σ_j and $(g, u_j)_Y$ against j and choose for λ the point where the two of them cross each other. For the case of the measurements in a test tank considered in this section, this plot is shown in Fig.11.4. Here one can recognise the usual behaviour of the singular values, i.e., they decrease, and the behaviour of the singular components which are expected to oscillate. The value of λ used in the truncation is indicated by the dashed lines. However, as seen in the previous Chapter, there exists a well-defined interval of allowed values for the cut-off parameter, centred at the value chosen above.

11.3 Measurements on a human chest

To make measurements on patients, a belt of electrodes is placed around their chest. It is important that the electrodes are equally spaced, since the reconstruction algorithm is dependent on their exact position.

For such measurements, there exist difficulties with the contact impedance. If currents are applied and voltages are measured on the same electrodes, the voltage measurements will be sensitive to the contact impedance which is formed at the electrode. To overcome this inconvenience, we have separated the electrodes measuring currents and potentials. If this technique is employed, no current flows through the voltage measurement electrodes, which means that no voltage is dropped across these electrodes, leading to more accurate voltage measurements across the sample.

The same tomograph was used, only now the sensing head was changed into a 16 double-electrode array. The double-electrodes consist of an outer gold-plated ring for current measurements and a middle, also gold-plated, pin for potential measurements (see Fig.11.5).

Once again, the reconstruction algorithm from Section 10.2 was used to produce pictures of the conductivity distribution inside the human body. Here, we have used “absolute” data, i.e., $\delta\phi$ (see Eq.(10.42)) was approximated by eliminating the frequency of the injected current from the Fourier spectrum of ϕ . As a regularisation

Figure 11.5: The double-electrode.

method the truncated singular value decomposition was implemented, with λ chosen like in the previous section.

One such reconstruction is shown in Fig.11.6. The corresponding plot of the singular values and singular components is shown in Fig.11.7, where the dashed lines correspond to the values chosen for λ . One can recognise the heart (high conductivity) and the lungs (low conductivity). Note that this is just a qualitative result. Remember that no reference measurement is at hand and that the background constant conductivity was approximated to 1, which is not the case in medical applications. Other potential sources of error are the inaccuracies in the location of electrodes. These inaccuracies may be in the non-uniformity in the spacing between the electrodes and/or in the shape of the boundary. However, these reconstructions may be useful even though the human volunteer is neither two-dimensional nor circular.

There is still a long way to go until actual medical applications, such as monitoring for lung problems, are possible. The resolution of the reconstruction should be improved, e.g. by using more electrodes and/or a more complex modelling of them (see Section 8.2). Also the time needed for a full cycle of measurements needs to be improved. For applications like the so-called “perfusion”, i.e., monitoring the blood flow to the lung tissue, a synchronisation of the measurements with the heart beat is needed.

Figure 11.6: Chest reconstruction on a human volunteer.

Conclusions and further work

QCD condensates from τ -decay data

Although QCD has been with us for three decades, the knowledge of the values of the various fundamental or effective parameters of the theory (with the possible exception of the coupling constant), such as quark masses and condensates, is still astonishingly limited. The precise data on τ -decay obtained by the ALEPH [ALEPH05] and OPAL [OPAL99] collaborations have offered an opportunity for new studies, which range from an extraction of the strange quark mass [Gu03] to the determination of various condensate parameters. The dimension $d = 6$ condensate was the most studied one [ALEPH98, ASS07, BDPS06, CGM03, CSSS04, DS04, IZ01, Na05, OPAL99, RL04, Zy04].

We have used a functional method which allows the extraction of condensates from experiment within rather general assumptions. It is obvious that it is an inverse problem: we want to determine constants of the theory which describe the hadronic structure, from indirect measurements. The data used for this purpose was the τ -decay data from the ALEPH collaboration [ALEPH05] at LEP. One has to relate error affected data in the time-like region to asymptotic QCD in the space-like region. This task of analytic continuation constitutes, mathematically, an ill-posed problem. In fact, extracting condensates from data is highly sensitive to data errors. Not surprisingly, results from different collaborations have not been always consistent.

The method consists in the comparison of the time-like experimental data with the asymptotic space-like QCD prediction in an L^2 -norm manner. Such a method must be well defined from a mathematical point of view and physically meaningful. One must give explicitly a quantitative estimate of the errors including both experimental and theoretical ones (truncation of the perturbative and operator product expansions). Then, a set of parameters is said to be *admissible* (or *compatible*, or *consistent*) if there exists at least one function with the required analytical properties which goes through the L^2 -error corridors. Answering to this question can be reduced to a minimisation process over a finite number of variables and to a sequence of Fredholm equations of the second kind, which leads to feasible computations.

We have performed 1- and 2-parameter fits using the data available for the $V - A$ channel. The first one was used for the extraction of the 4-quark condensate ($d = 6$) both at leading and next-to-leading order in α_s . The results are in agreement, within errors, with those from conventional analyses based on finite energy sum rules. An important result is obtained from the 2-parameter fit, where the free parameters are

the 4-quark ($d = 6$) and quark-gluon ($d = 8$) condensates. The strong correlation found allows one to determine a linear combination of the two condensates with a rather small error, in the order of 3%.

We have also performed 1- and 2-parameter fits for the V , A and $V + A$ channels separately. Here, the 1-parameter fit estimates the gluon condensate ($d = 4$) while from the 2-parameter fit a correlation between the gluon and 4-quark condensates is found. Again, on the basis of this correlation, one can determine combinations of the two condensates with rather small errors.

We would like to continue the research on this line and:

- Perform 3-parameter fits in all channels.
- Include contributions omitted in the present analysis like heavy quarks, broken chiral symmetry and duality violation. Such contributions may become important for a better stabilisation of the algorithm, i.e., for a more stable and continuous dependence of the algorithm (and results) on parameters like the end points of the space-like interval Γ_L and the number N of data points actually used in the analysis.
- To improve the precision and test the consistency, we would like to merge the results, find overall correlations and allowed ranges;
- It would be also interesting to compare, by means of the algorithm presented in this thesis, the τ -decay data with the data from e^+e^- -annihilation and, possibly, resolve the discrepancy between them.

The inverse conductivity problem

We have developed an approach for solving the inverse conductivity problem based on reformulating it in terms of integral equations and applied it to a two-dimensional domain, the unit disc, using no *a priori* information. Unfortunately, the information gained on the reconstructed conductivity distribution is restricted to its angular dependence (no radial information is present). One can only hope that using some *a priori* information could improve the reconstruction.

Also an algorithm based on linearisation was presented and tested both on “exact” (data produced by solving the forward problem) and real data. A promising result is that measurements on a human chest, taken with the tomograph constructed in collaboration with Dr. K.H. Georgi and N. Schuster, yield fairly good reconstructions. These results, even though they are just qualitative, encouraged us in believing that such an algorithm is useful in medical applications like monitoring for lung problems and thus intend to continue our research in this direction:

- We would like to improve the resolution of the reconstruction by, e.g., using more electrodes and/or a more complex modelling for them (e.g. the complete model);

-
- Improve the time needed for a full measurement cycle and for the reconstructions;
 - Synchronise the measurements with the heart beat, so that one can monitor the blood flow to the lung tissue.

Both approaches presented are geometrically constrained by requiring the availability of Neumann Green's function for the Laplace equation, which essentially restricts us to rectangular, circular, spherical, cylindrical or half-plane geometries. It is a challenging idea to remove this constraint and develop similar approaches using the free Green's function.

Appendices

Linear integral equations

Integral equations are equations in which an unknown function appears under one or more integral signs. They occur naturally in many fields of mathematical physics. They also arise as representation formulas for the solutions of differential equations. Indeed, a differential equation can be replaced by an integral equation which incorporates its boundary conditions. Then, each solution of the integral equation automatically satisfies these boundary conditions. Integral equations also form one of the most useful tools in many branches of pure analysis, such as the theories of functional analysis and stochastic processes.

We shall first give a classification of integral equations and afterwards concentrate on Fredholm integral equations which are among the most popular ones. We will consider some specific cases of Fredholm equations of the second kind and aim to find their solution. For the Fredholm equations of the first kind, only the case of symmetric kernels is considered. Based on the solution for this specific case, we argue that integral equations of the first kind can have properties characteristic to ill-posedness. For a more detailed theory one can consult for example [CH53a, Wy28].

The short theory of integral equations presented here was very useful throughout the entire work. In Chapter 5 we introduced an integral equation of the second kind which needed to be solved for some specific cases (Chapters 6 and 7). When we studied the kernel of this equation in more detail, it turned out that we deal with Fredholm integral equations of the second kind. Later on, in Chapter 9, Fredholm equations of second kind arose again when solving the direct problem of EIT. As concerning Fredholm equations of the first kind and their ill-posedness, they were needed for the reconstruction of conductivities inside a specified domain from a single set of measurements (see Section 10.1).

A.1 Types of integral equations

Fredholm equations represent one of the most important classes of linear integral equations. We shall distinguish between Fredholm equations of the first and second kind. Equations of the *second kind* are the most interesting and important in applications. The simplest formulation for such equations is

$$f(x) = u(x) - \lambda \int_a^b K(x, t)u(t)dt. \quad (\text{A.1})$$

Here, the unknown function $u(x)$ is a function of the real variable x which, along with t , is defined on the interval $[a, b]$. The interval $[a, b]$ may be finite or infinite. The

functions $K(x, t)$ and $f(x)$ are known and defined almost everywhere on $a \leq x, t \leq b$ and $a \leq x \leq b$, respectively. $K(x, t)$ is called the kernel of (A.1) and λ is a parameter. For Fredholm equations, $K(x, t)$ satisfies

$$\int_a^b \int_a^b |K(x, t)|^2 dx dt < \infty, \quad (\text{A.2})$$

and $f(x)$ satisfies

$$\int_a^b |f(x)|^2 dx < \infty. \quad (\text{A.3})$$

If $f(x) \equiv 0$ (or, more precisely, if $f(x)$ vanishes almost everywhere on $[a, b]$), then Eq.(A.1) is said to be *homogeneous*, otherwise *non-homogeneous*.

Fredholm equations of the *first kind* differ from the second kind in that the isolated term, $u(x)$, in (A.1) is absent. The simplest form for it is:

$$f(x) = \lambda \int_a^b K(x, t)u(t)dt, \quad (\text{A.4})$$

where $K(x, t)$ and $f(x)$ satisfy Eqs. (A.2) and (A.3), respectively.

If the kernel of the integral equation has the form

$$K(x, t) = \frac{H(x, t)}{|x - t|^\alpha}, \quad (\text{A.5})$$

where $H(x, t)$ is bounded and $0 < \alpha < 1$, Eq.(A.1) will be called an *integral equation with a weak singularity*.

When the kernel under consideration is of the form

$$K(x, t) = \frac{A(x, t)}{x - t}, \quad (\text{A.6})$$

where the numerator $A(x, t)$ is a differentiable function of x and t and if the divergent integral is interpreted in the sense of its principal value, Eq.(A.1) is called a *singular integral equation*.

Volterra equations of the first, homogeneous and second kinds are defined precisely as above, except that $b = x$ is the variable upper limit of integration. There exist also other classes of integral equations, e.g. equations with convolution kernels, Wiener-Hopf equations, dual equations, integral transforms and non-linear integral equations. However, we shall consider here only the case of Fredholm equations.

A.2 Equations of the second kind

We will start with integral equations of the second kind since they appear to be the easiest in the discussion. We will study a few specific cases, as concerning the properties of the kernel, for which a compact solution can be found and also give a solution by means of Neumann series.

A.2.1 Degenerate kernels

A kernel, which can be written as a finite sum of products of linearly independent functions of x and linearly independent functions of t ,

$$K(x, t) = \sum_{i=1}^p a_i(x)b_i(t), \quad (\text{A.7})$$

is called a degenerate kernel. With the help of this representation and exchanging summation with integration, Eq.(A.1) becomes:

$$f(x) = u(x) - \lambda \sum_{i=1}^p a_i(x) \int_a^b b_i(t)u(t)dt. \quad (\text{A.8})$$

One can show that the solution of this Fredholm integral equation reduces to solving a system of linear equations. Indeed, if we define c_i as the integral in (A.8)

$$c_i = \int_a^b b_i(t)u(t)dt, \quad (\text{A.9})$$

multiply both sides of (A.8) by $b_m(x)$ and integrate over x from a to b , we find:

$$f_m = c_m - \lambda \sum_{i=1}^p a_{mi}c_i, \quad m = 1, 2, \dots, p, \quad (\text{A.10})$$

where

$$f_m = \int_a^b b_m(x)f(x)dx, \quad (\text{A.11})$$

and

$$a_{mi} = \int_a^b b_m(x)a_i(x)dx. \quad (\text{A.12})$$

Eq.(A.12) is a set of p linear equations in c_1, c_2, \dots, c_p which can be solved by usual methods.

A.2.2 Symmetric kernels

The theory of integral equations can be developed in greater detail if the kernel $K(x, t)$ is symmetric, i.e., if it satisfies the relation

$$K(x, t) = K(t, x). \quad (\text{A.13})$$

Theorem A.1 *Every continuous symmetric kernel that does not vanish identically possesses eigenvalues and eigenfunctions; their number is denumerably infinite if and only if the kernel is non-degenerate. All the eigenvalues of a real symmetric kernel are real.*

Proof: The proof is made in several steps:

1. Prove the existence of an eigenvalue of a symmetric kernel;
2. Consider the totality of eigenfunctions and eigenvalues;
3. Finally prove that all the eigenvalues are real.

For further details see [CH53a]. □

Theorem A.2 *Every continuous function $g(x)$ which is an integral transform with symmetric kernel $K(x, t)$ of a piecewise continuous function $h(t)$*

$$g(x) = \int_a^b K(x, t)h(t)dt, \quad (\text{A.14})$$

can be expanded in a series in the eigenfunctions of $K(x, t)$

$$g(x) = \sum_{i=1}^{\infty} g_i \varphi_i(x), \quad g_i = (g, \varphi_i) = \frac{(h, \varphi_i)}{\lambda_i}; \quad (\text{A.15})$$

this series converges uniformly and absolutely. □

Setting now $h(y) = K(y, t)$, for the 'iterated kernel'

$$K^{(2)}(x, t) = \int_a^b K(x, y)K(y, t)dy \quad (\text{A.16})$$

we then have the expansion

$$K^{(2)}(x, t) = \sum_{i=1}^{\infty} \frac{\varphi_i(x)}{\lambda_i} \int_a^b K(y, t)\varphi_i(y)dy \quad (\text{A.17})$$

or

$$K^{(2)}(x, t) = \sum_{i=1}^{\infty} \frac{\varphi_i(x)\varphi_i(t)}{\lambda_i^2} \quad (\text{A.18})$$

In the same way, the subsequent iterated kernels

$$K^{(n)}(x, t) = \int_a^b K^{(n-1)}(x, y)K(y, t)dy \quad (\text{A.19})$$

admit the expansions

$$K^{(n)}(x, t) = \sum_{i=1}^{\infty} \frac{\varphi_i(x)\varphi_i(t)}{\lambda_i^n} \quad (n = 2, 3, \dots), \quad (\text{A.20})$$

all of which converge absolutely and uniformly both in x and in t , and uniformly in x and t together.

However, such an expansion for the full kernel,

$$K(x, t) = \sum_{i=1}^{\infty} \frac{\varphi_i(x)\varphi_i(t)}{\lambda_i}, \quad (\text{A.21})$$

does not always exist.

We can now derive the formula for the solution of the inhomogeneous integral equation (A.1) for a symmetric kernel $K(x, t)$ which admits the eigenfunction expansion (A.21). We assume initially that the parameter λ is not equal to any of the eigenvalues λ_i . If the continuous function u with the expansion coefficients (u, φ_i) were a solution of the integral equation, then, by the expansion theorem applied to $\lambda u(t)$, the function $u(x) - f(x) = g(x)$ would be given by the uniformly and absolutely convergent series

$$g(x) = u(x) - f(x) = \sum_{i=1}^{\infty} c_i \varphi_i(x) = \lambda \int_a^b K(x, t)u(t)dt, \quad (\text{A.22})$$

where

$$c_i = (g, \varphi_i) = \lambda \int_a^b \int_a^b K(x, t)\varphi_i(x)u(t)dxdt = \frac{\lambda}{\lambda_i}(\varphi_i, u) = \frac{\lambda}{\lambda_i}(\varphi_i, f) + \frac{\lambda}{\lambda_i}(\varphi_i, g) \quad (\text{A.23})$$

from which it follows that

$$c_i = f_i \frac{\lambda}{\lambda_i - \lambda}, \quad (f_i = (\varphi_i, f)). \quad (\text{A.24})$$

We thus obtain the series expansion for u ,

$$u(x) = f(x) + \lambda \sum_{i=1}^{\infty} \frac{f_i}{\lambda_i - \lambda} \varphi_i(x), \quad (\text{A.25})$$

which must represent the solution of (A.1). This solution fails only if $\lambda = \lambda_i$ is an eigenvalue; it remains valid even in this case if $f(x)$ is orthogonal to all eigenfunctions φ_i belonging to the eigenvalue λ_i .

A.2.3 Neumann series and the reciprocal kernel

The theorems of integral equations given above imply a prescription for actually computing solutions with arbitrary accuracy. It does not give the solutions, however, in an elegant closed form as in the previous section.

We write the integral equation (A.1), inserting in place of $u(t)$ in the integral the expression obtained from (A.1), and iterate this procedure. With the aid of the

iterated kernels we thus write (A.1) in the form

$$\begin{aligned} u(x) &= f(x) + \lambda \int_a^b K(x,t)f(t)dt + \lambda^2 \int_a^b K^{(2)}(x,t)u(t)dt \\ &= f(x) + \lambda \int_a^b K(x,t)f(t)dt + \lambda^2 \int_a^b K^{(2)}(x,t)f(t)dt \\ &\quad + \lambda^3 \int_a^b K^{(3)}(x,t)u(t)dt \\ &= \dots \end{aligned}$$

and see that the solution is given by the infinite series

$$u(x) = f(x) + \lambda \int_a^b K(x,t)f(t)dt + \lambda^2 \int_a^b K^{(2)}(x,t)f(t)dt + \dots, \quad (\text{A.26})$$

provided that this series converges uniformly. If, moreover, the series

$$\mathcal{K}(x,t) = K(x,t) + \lambda K^{(2)}(x,t) + \lambda^2 K^{(3)}(x,t) + \dots \quad (\text{A.27})$$

also converges uniformly then the solution of the integral equation (A.1),

$$f(x) = u(x) - \lambda \int_a^b K(x,t)u(t)dt, \quad (\text{A.28})$$

is represented by the '*reciprocal integral equation*'

$$u(x) = f(x) + \lambda \int_a^b \mathcal{K}(x,t)f(t)dt. \quad (\text{A.29})$$

The function $\mathcal{K}(x,t) = \mathcal{K}(x,t;\lambda)$ is therefore called the *reciprocal* or *resolvent* kernel.

Series (A.26) and (A.27) are known as *Neumann's series*. They converge uniformly if $|\lambda|$ is sufficiently small. Thus, for sufficiently small $|\lambda|$, the reciprocal kernel is an analytic function of λ .

If the kernel $K(x,t)$ is symmetric we can find a remarkably simple form for the resolvent kernel. Assuming again $|\lambda|$ to be sufficiently small, we make use of the series expansion (A.20) for the symmetric kernels $K^{(2)}(x,t), K^{(3)}(x,t), \dots$ and take the sum of the geometric series occurring in (A.27); we immediately obtain

$$\mathcal{K}(x,t;\lambda) = K(x,t) + \lambda \sum_{i=1}^{\infty} \frac{\varphi_i(x)\varphi_i(t)}{\lambda_i(\lambda_i - \lambda)}. \quad (\text{A.30})$$

We see that the series on the right converges for every value of λ which is not an eigenvalue, and the convergence is uniform in x and t .

Relation (A.30) which has been proved only for sufficiently small $|\lambda|$ provides the analytic continuation of the resolvent $\mathcal{K}(x,t;\lambda)$ into the entire complex λ -plane, with the eigenvalues λ_i appearing as simple poles. Thus *the resolvent of a symmetric kernel is a meromorphic function of λ which possesses simple poles at the eigenvalues of the integral equation*. Its residues at the poles λ_i provide the eigenfunctions belonging to these eigenvalues.

A.3 Equations of the first kind

Before trying to solve Fredholm integral equations of the first kind (A.4) we may first ask whether a solution does exist at all. We emphasise this point, since the theory is rather restrictive for the existence of solutions if compared to that of Fredholm equations of the second kind.

The difficulty of finding a solution for the Fredholm integral equation (A.4) stems from the fact that the integration operation over the sought solution $u(t)$, is a smoothing process, especially, when combined with a nicely behaved kernel $K(x, t)$. This means, for example, that if the solution $u(x)$ is piecewise continuous, then the above integration operation on the r.h.s. of (A.4), with a continuous kernel $K(x, t)$, would result in a smoother, i.e., continuous output $f(x)$ of (A.4), as the given function at hand. So, if we are given a continuous function $f(x)$, we cannot, in general guarantee an answer in the search for a solution $u(x)$ among the class of continuous functions! In other words, if we look at the r.h.s. of (A.4) as an integral transform of piecewise continuous functions, then this transform maps such a class of functions to a more restrictive one, in this case continuous functions. Indeed, for more smooth kernels, i.e., if $K(x, t)$ is differentiable, the class of piecewise or even integrable functions $u(t)$ is mapped into differentiable functions $f(x)$. Hence, for a continuous kernel $K(x, t)$ (in both x and t) and a continuous output $f(x)$, the integral equation of the first kind (A.4) cannot, in general, be solved by a continuous function $u(t)$. Of course, if $K(x, t)$ is not very regular, then it is possible that this irregularity is combined with the smoothness of the integration operation and a continuous solution $u(t)$, to produce a continuous output $f(x)$.

Theorem A.3 *For a continuous real and symmetric kernel, and a continuous $f(x)$, a solution to (A.4) exists only if the given function $f(x)$ can be expressed in a series of the eigenfunctions of the kernel $K(x, t)$, i.e., only if*

$$f(x) = \sum_{k=1}^{\infty} a_k \varphi_k(x), \quad a_k = \int_a^b f(x) \varphi_k(x) dx, \quad (\text{A.31})$$

where we have used the orthonormal set of eigenfunctions $\{\varphi_k(x)\}$ on $[a, b]$. \square

With the condition stated in this theorem, the solution of (A.4) takes the form

$$u(x) = \sum_{k=1}^{\infty} \lambda_k a_k \varphi_k(x). \quad (\text{A.32})$$

We may note here that, although the existence of the (continuous) solution of (A.4) in the form of the series (A.32) is guaranteed, it is by no means a unique solution. This is the case, since if we add to the series in (A.32) a function $\psi(x)$ that is orthogonal to the kernel $K(x, t)$, i.e.,

$$\int_a^b K(x, t) \psi(t) dt = 0, \quad (\text{A.33})$$

and substitute in (A.4), we obtain the same output $f(x)$. So, for a unique solution $u(x)$ in (A.32), we must insist that there are no functions $\psi(x)$ that are orthogonal to the symmetric kernel $K(x, t)$.

The general case is covered by a theorem of Picard [Pi10] which gives necessary and sufficient conditions for the existence of a square integrable solution $u(t)$ of an equation of the first kind with an arbitrary (possibly unsymmetric) kernel.

It is also useful to remark that Fredholm integral equations of the first kind can easily show the characteristics of ill-posedness defined in Section 1.3. We have just established a unique solution for Fredholm equations of the first kind for the specific case of symmetric kernels. What remains, for the present discussion, is the question whether the third quality, the stability of the solution of the problem, can also be established. Unfortunately, from the solution $u(x)$ in (A.32) we can show that the problem is not stable. When perturbing the given data $f(x)$ by a small $\delta f(x)$ we expect the solution $u(x)$, in its series representation (A.32), to be perturbed by a series representation of $\delta f(x)$ (or a constant multiple of it). However, one finds a magnification, i.e., a much larger corresponding change δu in $u(x)$. This is due to the eigenvalues λ_k factor in (A.32), where they are increasing. If we write (A.32), using the explicit form for a_k , we have

$$u(x) = \sum_{k=1}^{\infty} \lambda_k \varphi_k(x) \int_a^b f(y) \varphi_k(y) dy. \quad (\text{A.34})$$

Now, if we perturb $f(x)$ by $\delta f(x)$ we get

$$\begin{aligned} u(x) + \delta u(x) &= \sum_{k=1}^{\infty} \lambda_k \varphi_k(x) \int_a^b [f(y) + \delta f(y)] \varphi_k(y) dy \\ &= \sum_{k=1}^{\infty} \lambda_k \varphi_k(x) \int_a^b f(y) \varphi_k(y) dy + \sum_{k=1}^{\infty} \lambda_k \varphi_k(x) \int_a^b \delta f(y) \varphi_k(y) dy, \end{aligned} \quad (\text{A.35})$$

$$\delta u(x) = \sum_{k=1}^{\infty} \lambda_k \epsilon_k \varphi_k(x), \quad \epsilon_k = \int_a^b \delta f(y) \varphi_k(y) dy, \quad (\text{A.36})$$

where ϵ_k is the above expansion coefficient of the small perturbation $\delta f(x)$. In (A.36) we see that the expansion coefficients corresponding to the perturbation δu are magnified by a multiplicative factor λ_k , increasing with k , which clearly will cause $\delta u(x)$ to be a larger change compared to the given small change $\delta f(x)$. Hence, it seems that the solution $u(x)$ is not stable in the Fredholm equation of the first kind (A.4). This possible ill-posedness adds to other difficulties for the existence of solutions for problems with more general kernels. It is no surprise that Fredholm integral equations of the first kind are in the forefront with regard to the research priority in the field of integral equations.

Green's function

Green's functions provide a useful tool for dealing with source terms in differential equations. They are named after the British mathematician George Green, who first developed the concept in the 1830s. In this short overview we will present the general theory concerning the ordinary differential equations. The theory for partial differential equations is similar and it will not be treated here. Instead, some examples of the Green's function for the Laplace equation are presented. Finally, the Neumann Green's function for the unit disc is discussed in more detail. An elaborate theory of Green's functions can be found for example in [CH53a, Wy28].

Throughout the present work, the method of Green's function was used to transform the partial differential equation governing the EIT into an integral equation (Chapters 9 and 10). Furthermore, the Neumann Green's function is needed in Chapter 10 to solve these equations for the particular case of the unit disc.

B.1 General theory

Let us consider a linear homogeneous self-adjoint differential expression of second order

$$Lu = \frac{d}{dx} \left[p \frac{du}{dx} \right] - qu, \quad (\text{B.1})$$

for the function $u(x)$ in the fundamental domain Ω : $a \leq x \leq b$, where p , dp/dx and q are continuous functions of x and $p > 0$. The associated non-homogeneous differential equation is of the form

$$Lu = \varphi(x), \quad (\text{B.2})$$

where $\varphi(x)$ denotes a piecewise continuous function defined in Ω . We are concerned with the boundary value problem: *Find a solution of Eq.(B.2) which satisfies given homogeneous boundary conditions at the boundary of Ω .*

For L we have the Green's theorem identity:

$$\int_a^b dx [vLu - uLv] = \left[p \left(v \frac{du}{dx} - u \frac{dv}{dx} \right) \right]_a^b. \quad (\text{B.3})$$

In order to solve Eq.(B.2) for a general source $\varphi(x)$ we introduce the so called Green's function $G(x, x')$, which is the solution for a point source at x' :

$$LG(x, x') = \delta(x - x'), \quad (\text{B.4})$$

$\delta(x - x')$ being the Dirac delta function. We then use the linear character of (B.1) to find the solution for a source $\varphi(x)$ by superposition:

$$u(x) = \int_a^b dx' G(x, x') \varphi(x'). \quad (\text{B.5})$$

In order to elaborate on the previous remarks, with suitable attention to the boundary conditions, let us suppose that the solution of (B.4) can be found. First, let us apply Green's theorem (B.3) to u and $v = G$:

$$\begin{aligned} \int_a^b dx [G(x, x') Lu(x) - u(x) LG(x, x')] \\ = \left[p(x) \left(G(x, x') \frac{du(x)}{dx} - u(x) \frac{d}{dx} G(x, x') \right) \right]_a^b \\ = \int_a^b dx G(x, x') \varphi(x) - u(x'), \end{aligned} \quad (\text{B.6})$$

where we have used (B.2), (B.4) and the integral properties of the delta function. Interchanging x and x' we find

$$u(x) = \int_a^b dx' G(x', x) \varphi(x') - \left[p(x') \left(G(x', x) \frac{du(x')}{dx'} - u(x') \frac{d}{dx'} G(x', x) \right) \right]_a^b. \quad (\text{B.7})$$

We can now consider several possibilities for the boundary conditions on $u(x)$ at $x = a, b$.

1. $u(a)$ and $u(b)$ given.

For this case choose as boundary conditions on $G(x', x)$

$$G(a, x) = G(b, x) = 0. \quad (\text{B.8})$$

This has the desirable advantage of eliminating from Eq.(B.7) the unknown quantities du/dx' at $x' = a, b$. In fact (B.7) reduces to

$$u(x) = \int_a^b dx' G(x', x) \varphi(x') + \left[p(x') u(x') \frac{d}{dx'} G(x', x) \right]_a^b. \quad (\text{B.9})$$

This is the solution of Eq.(B.2) in terms of known quantities.

2. $u(a)$ and $u'(b)$ given.

For this case choose as boundary conditions on $G(x', x)$

$$G(a, x) = 0, \quad \left. \frac{d}{dx'} G(x', x) \right|_{x'=b} = 0. \quad (\text{B.10})$$

Again the unknown quantities, in this case $u(b)$ and du/dx at $x = a$ are eliminated from Eq.(B.7) and we obtain the solution of (B.2) in terms of known quantities:

$$u(x) = \int_a^b dx' G(x', x) \varphi(x') - p(a)u(a) \left. \frac{d}{dx'} G(x', x) \right|_{x'=a} - p(b)G(b, x) \left. \frac{du}{dx'} \right|_{x'=b}. \quad (\text{B.11})$$

3. $Au(a) + Bu'(a) = X$ and $Cu(b) + Du'(b) = Y$ given.

Choose

$$\begin{aligned} AG(a, x) + B \left. \frac{d}{dx} G(x', x) \right|_{x'=a} &= 0, \\ CG(b, x) + D \left. \frac{d}{dx} G(x', x) \right|_{x'=b} &= 0. \end{aligned} \quad (\text{B.12})$$

The quantity needed in (B.7) at $x' = a$ is then

$$\begin{aligned} G(a, x) \left. \frac{du(x')}{dx'} \right|_{x'=a} - u(a) \left. \frac{d}{dx'} G(x', x) \right|_{x'=a} \\ &= G(a, x) \left. \frac{du(x')}{dx'} \right|_{x'=a} - u(a) \left[-\frac{A}{B} G(a, x) \right] \\ &= \frac{G(a, x)}{B} \left[Au(a) + B \left. \frac{du(x')}{dx'} \right|_{x'=a} \right] \\ &= \frac{G(a, x)}{B} X \\ &= -\frac{1}{A} \left. \frac{d}{dx'} G(x', x) \right|_{x'=a} X, \end{aligned} \quad (\text{B.13})$$

which is a known quantity. A similar manipulation shows that the quantity needed at $x' = b$ in (B.7) can be expressed in terms of the given quantity Y .

In each case we can choose the boundary conditions on G so as to eliminate unknown values of u and u' at the boundaries. In this way we obtain a solution of the inhomogeneous differential equation (B.2) once we find the Green's function $G(x', x)$.

We can prove that the Green's function is symmetric in its two arguments. To see this, apply the Green's theorem (B.3) to $u(x) = G(x, x')$ and $v(x) = G(x, x'')$. Using Eq.(B.4) we find

$$G(x', x'') - G(x'', x') = \left[p(x) \left(G(x, x'') \frac{d}{dx} G(x, x') - G(x, x') \frac{d}{dx} G(x, x'') \right) \right]_a^b. \quad (\text{B.14})$$

For the general case with boundary conditions (B.12) the r.h.s. of Eq.(B.14) vanishes and we find

$$G(x', x'') = G(x'', x'). \quad (\text{B.15})$$

Let us now return to the differential equation (B.4) for $G(x, x')$:

$$\frac{d}{dx} \left[p(x) \frac{d}{dx} G(x, x') \right] - q(x)G(x, x') = \delta(x - x'). \quad (\text{B.16})$$

For $x \neq x'$ this reduces to the homogeneous equation

$$\frac{d}{dx} \left[p(x) \frac{d}{dx} G(x, x') \right] - q(x)G(x, x') = 0, \quad x \neq x', \quad (\text{B.17})$$

so we can use whatever techniques are available for homogeneous equations in solving for $G(x, x')$ in the two regions $x > x'$ and $x < x'$. At $x = x'$ we must match the two solutions so obtained. The delta function $\delta(x - x')$ on the r.h.s. of (B.16) is to be interpreted as due to a discontinuity in $dG(x, x')/dx$ at $x = x'$. In fact, integrating (B.16) over an interval $x = x' - \varepsilon$ to $x = x' + \varepsilon$ of infinitesimal length about $x = x'$ and assuming $q(x)G(x, x')$ is finite in this region so that

$$\int_{x'-\varepsilon}^{x'+\varepsilon} dx q(x)G(x, x') \xrightarrow{\varepsilon \rightarrow 0} 0, \quad (\text{B.18})$$

we find

$$\frac{d}{dx} G(x, x') \Big|_{x'-\varepsilon}^{x'+\varepsilon} = \frac{1}{p(x')}, \quad (\text{B.19})$$

provided $p(x)$ is continuous at $x = x'$. On the other hand, we must take $G(x, x')$ to be continuous at $x = x'$:

$$G(x' + \varepsilon, x') = G(x' - \varepsilon, x'). \quad (\text{B.20})$$

If there were a discontinuity in $G(x, x')$ itself, the first derivative $dG(x, x')/dx$ would contain a term proportional to $\delta(x - x')$ and the second derivative $d^2G(x, x')/dx^2$ a term proportional to $d\delta(x - x')/dx$, in contradiction to the defining Eq.(B.16).

The homogeneous Eq.(B.17) in the two regions $x < x'$ and $x > x'$ together with the two conditions (B.19) and (B.20) at $x = x'$ and the boundary conditions at $x = a$ and $x = b$ discussed previously, completely determine the Green's function, the four conditions fixing the two pairs of integration constants obtained on solving the differential equation in the two regions.

In the case of partial differential equations with homogeneous boundary conditions, Green's function can again be introduced as the kernel of an equivalent integral equation with the same properties as in the case of the ordinary differential equations [CH53a]. We will not repeat the theory, but rather give some examples.

B.2 Examples of Green's function for partial differential equations

Let us consider the Laplace equation for a two-dimensional domain Ω

$$\Delta\phi(\mathbf{x}) = 0, \quad \text{with } \Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}, \quad (\text{B.21})$$

the Laplace operator. In the following we will consider a few special cases:

- Choose G_0 to be the fundamental (free) Green's function, satisfying:

$$\Delta_{\mathbf{x}}G_0(\mathbf{x}, \mathbf{x}') = -\delta(\mathbf{x} - \mathbf{x}') \quad \text{for } \mathbf{x}, \mathbf{x}' \in \Omega. \quad (\text{B.22})$$

This function is independent of the shape of Ω and for a two-dimensional space it is:

$$G_0(\mathbf{x}, \mathbf{x}') = -\frac{1}{2\pi} \log |\mathbf{x} - \mathbf{x}'|. \quad (\text{B.23})$$

- Define G_D to be the Dirichlet Green's function given by

$$\begin{cases} \Delta_{\mathbf{x}}G_D(\mathbf{x}, \mathbf{x}') = -\delta(\mathbf{x} - \mathbf{x}') & \text{for } \mathbf{x}, \mathbf{x}' \in \Omega \\ G_D(\mathbf{x}, \mathbf{x}') = 0 & \text{for } \mathbf{x} \in \partial\Omega \text{ and } \mathbf{x}' \in \Omega \end{cases} \quad (\text{B.24})$$

In contrast to G_0 , G_D depends on the shape of Ω and the difference between them is a harmonic term. For a disc of radius R , G_D is given by the formula

$$G_D(r, \theta; r', \theta') = -\frac{1}{4\pi} \log \left[\frac{r^2 + r'^2 - 2rr' \cos(\theta - \theta')}{R^2 + \frac{r^2}{R^2}r'^2 - 2rr' \cos(\theta - \theta')} \right], \quad (\text{B.25})$$

where (r, θ) and (r', θ') are the polar coordinates associated to \mathbf{x} and \mathbf{x}' respectively.

- Now consider G_N to be the Neumann Green's function which obeys the conditions:

$$\begin{cases} \Delta_{\mathbf{x}}G_N(\mathbf{x}, \mathbf{x}') = -\delta(\mathbf{x} - \mathbf{x}') + \frac{1}{|\Omega|} & \text{for } \mathbf{x}, \mathbf{x}' \in \Omega \\ \frac{\partial G_N}{\partial n}(\mathbf{x}, \mathbf{x}') = 0 & \text{for } \mathbf{x} \in \partial\Omega \text{ and } \mathbf{x}' \in \Omega \end{cases} \quad (\text{B.26})$$

where $|\Omega|$ is the volume of the domain Ω . Like G_D , G_N also depends on the shape of the domain Ω and differs from G_0 by a harmonic term. For a disc of radius R , G_N reads:

$$\begin{aligned} G_N(r, \theta; r', \theta') = & -\frac{1}{4\pi} \log \left[r^2 + r'^2 - 2rr' \cos(\theta - \theta') \right] \\ & -\frac{1}{4\pi} \log \left[R^2 + \frac{r^2}{R^2}r'^2 - 2rr' \cos(\theta - \theta') \right], \end{aligned} \quad (\text{B.27})$$

where by (r, θ) and (r', θ') we denoted again the polar coordinates associated to \mathbf{x} and \mathbf{x}' respectively.

B.3 Neumann Green's function for the unit disc

The eigenvalue problem

$$\begin{cases} \Delta v + \lambda v = 0, \\ \left. \frac{\partial v}{\partial r} \right|_{r=1} = 0, \end{cases} \quad (\text{B.28})$$

defines the eigenfunctions v_n of the Neumann Green's function, Eq.(B.27), assumed to have the eigenvalue expansion:

$$G_N(\mathbf{x}, \mathbf{x}') = \sum_n \frac{v_n(\mathbf{x})v_n(\mathbf{x}')}{\lambda_n}. \quad (\text{B.29})$$

The Laplacian in polar coordinates reads:

$$\Delta = \frac{1}{r} \left[\frac{\partial}{\partial r} \left(r \frac{\partial}{\partial r} \right) + \frac{\partial}{\partial \theta} \left(\frac{1}{r} \frac{\partial}{\partial \theta} \right) \right]. \quad (\text{B.30})$$

Let us search for solutions of (B.28) of the form $v(r, \theta) = f(r)u(\theta)$:

$$\begin{cases} \frac{d^2 u}{d\theta^2} + l^2 u = 0 \\ \frac{1}{r} \frac{df}{dr} + \frac{d^2 f}{dr^2} + \left(\lambda - \frac{l^2}{r^2} \right) f = 0, \quad \left. \frac{df}{dr} \right|_{r=1} = 0 \end{cases} ; \quad l \in \mathbb{N}_+. \quad (\text{B.31})$$

The solutions of the first equation are just the well-known eigenfunctions for the unit circle

$$u_l^j(\theta) = \frac{1}{\sqrt{\pi(1 + \delta_{l0})}} \begin{cases} \sin l\theta & \text{for } j = 1 \\ \cos l\theta & \text{for } j = 2 \end{cases} ; \quad l \in \mathbb{N}_+. \quad (\text{B.32})$$

To solve the second equation in (B.31), we make the change of variable:

$$kr = \rho \quad \text{with} \quad \lambda = k^2, \quad (\text{B.33})$$

and find Bessel's equation

$$\frac{1}{\rho} f'(\rho) + f''(\rho) + \left(1 - \frac{l^2}{\rho^2} \right) f(\rho) = 0, \quad (\text{B.34})$$

which has the regular solution

$$f(\rho) = J_l(\rho) = J_l(kr), \quad (\text{B.35})$$

where J_l are the Bessel functions. Imposing the boundary condition (see Eq.(B.26)), one finds

$$kJ_l'(k) = 0 \quad (\text{B.36})$$

and thus k are the zeros of the first derivative of J_l , usually denoted j_{lm}^* . The eigenfunctions corresponding to the eigenvalues $\lambda = (j_{lm}^*)^2$ will then be

$$f_l(r) = J_l(j_{lm}^* r). \quad (\text{B.37})$$

One still has to normalise them. Recalling that

$$\int_0^1 J_l^2(j_{lm}^* r) dr = \frac{1}{2} \left(1 - \frac{l^2}{j_{lm}^{*2}} \right) J_l^2(j_{lm}^*), \quad (\text{B.38})$$

the normalisation constants become

$$C_{lm} = \sqrt{\frac{2}{1 - l^2/j_{lm}^{*2}}} \frac{1}{|J_l(j_{lm}^*)|}. \quad (\text{B.39})$$

Finally, the eigenfunctions corresponding to the eigenvalues $\lambda = (j_{lm}^*)^2$, defined by the boundary eigenvalue problem (B.28), are:

$$v_{lm}^j(r, \theta) = \frac{C_{lm}}{\sqrt{\pi(1 + \delta_{l0})}} J_l(j_{lm}^* r) \begin{cases} \sin l\theta & \text{for } j = 1 \\ \cos l\theta & \text{for } j = 2 \end{cases}; \quad l \in \mathbb{N}_+, \quad (\text{B.40})$$

or shortly

$$v_{lm}^j(r, \theta) = C_{lm} J_l(j_{lm}^* r) u_l^j(\theta), \quad l \in \mathbb{N}_+, \quad (\text{B.41})$$

and the Neumann Green's function is

$$G_N(r, \theta; r', \theta') = \sum_{l,m=1}^{\infty} \sum_{j=1}^2 \frac{v_{lm}^j(r, \theta) v_{lm}^j(r', \theta')}{\lambda_{lm}}. \quad (\text{B.42})$$

On the boundary, i.e., on the unit circle, one has

$$G_N(1, \theta; 1, \theta') = \sum_{l=1}^{\infty} \sum_{j=1}^2 u_l^j(\theta) u_l^j(\theta') \sum_{m=1}^{\infty} \frac{2}{j_{lm}^{*2} - l^2}. \quad (\text{B.43})$$

Recalling that:

$$\sum_{m=1}^{\infty} \frac{2}{j_{lm}^{*2} - l^2} = \frac{1}{l}, \quad (\text{B.44})$$

one finds:

$$G_N(1, \theta; 1, \theta') = \sum_{l=1}^{\infty} \sum_{j=1}^2 \frac{1}{l} u_l^j(\theta) u_l^j(\theta'). \quad (\text{B.45})$$

SVD of an integral operator

One of the most fruitful tools in the theory of linear inverse problems is the singular value decomposition of a matrix and its extension to certain classes of linear operators. As we have seen in Chapter 2, SVD is basic both for understanding the ill-posedness of inverse problems and for describing the effect of the regularisation methods. Here, we will restrict the discussion to the SVD of integral operators with square-integrable kernel, needed in the EIT application of Section 10.1.

Let us define an integral operator of the following form:

$$(Af)(\mathbf{x}) = \int_{\Omega} K(\mathbf{x}, \mathbf{x}')f(\mathbf{x}')d\mathbf{x}', \quad \mathbf{x} \in \Omega' \quad (\text{C.1})$$

where Ω and Ω' are the object and the image domain respectively.

We assume, for simplicity, that both the object and the image are square-integrable functions of the space variables, so that we have $\mathcal{X} = L^2(\Omega)$ and $\mathcal{Y} = L^2(\Omega')$. Then Eq.(C.1) defines an operator from $L^2(\Omega)$ into $L^2(\Omega')$. This operator is continuous if the integral kernel is square-integrable, i.e.

$$\|K\|^2 = \int_{\Omega'} d\mathbf{x} \int_{\Omega} d\mathbf{x}' |K(\mathbf{x}, \mathbf{x}')|^2 < \infty. \quad (\text{C.2})$$

An integral operator satisfying this condition is usually called an integral operator of the *Hilbert-Schmidt class*.

In order to show that this operator is continuous we apply the Schwartz inequality to the r.h.s. of Eq.(C.1) which, for fixed \mathbf{x} , results in the scalar product of two square integrable functions. It follows

$$|(Af)(\mathbf{x})|^2 \leq \left(\int_{\Omega} |K(\mathbf{x}, \mathbf{x}')|^2 d\mathbf{x}' \right) \left(\int_{\Omega} |f(\mathbf{x}')|^2 d\mathbf{x}' \right). \quad (\text{C.3})$$

If we integrate both sides of this inequality with respect to \mathbf{x} , and take the square root of the result, we get

$$\|Af\|_{\mathcal{Y}} \leq \|K\| \cdot \|f\|_{\mathcal{X}}, \quad (\text{C.4})$$

i.e., the operator is bounded. This property implies the continuity of the operator.

The adjoint A^* of the operator A is given by

$$(A^*g)(\mathbf{x}') = \int_{\Omega'} K^*(\mathbf{x}, \mathbf{x}')g(\mathbf{x})d\mathbf{x}, \quad \mathbf{x}' \in \Omega. \quad (\text{C.5})$$

Then we can introduce the operators $\bar{A} = A^*A$ and $\tilde{A} = AA^*$. Both are integral operators with integral kernels given by

$$\bar{A}: \bar{K}(\mathbf{x}, \mathbf{x}') = \int_{\Omega'} K^*(\mathbf{x}'', \mathbf{x})K(\mathbf{x}'', \mathbf{x}')d\mathbf{x}''; \quad \mathbf{x}, \mathbf{x}' \in \Omega, \quad (\text{C.6})$$

$$\tilde{A}: \tilde{K}(\mathbf{x}, \mathbf{x}') = \int_{\Omega} K(\mathbf{x}, \mathbf{x}'')K^*(\mathbf{x}', \mathbf{x}'')d\mathbf{x}''; \quad \mathbf{x}, \mathbf{x}' \in \Omega'. \quad (\text{C.7})$$

The integral operators \bar{A} , \tilde{A} have the following properties:

- Both operators are self-adjoint, i.e., for any pair of functions f, h in \mathcal{X} and any pair of functions g, w in \mathcal{Y}

$$(\bar{A}f, h)_{\mathcal{X}} = (f, \bar{A}h)_{\mathcal{X}}, \quad (\tilde{A}g, w)_{\mathcal{Y}} = (g, \tilde{A}w)_{\mathcal{Y}}. \quad (\text{C.8})$$

This property is a consequence of the following relations

$$\bar{K}^*(\mathbf{x}, \mathbf{x}') = \bar{K}(\mathbf{x}', \mathbf{x}), \quad \tilde{K}^*(\mathbf{x}, \mathbf{x}') = \tilde{K}(\mathbf{x}', \mathbf{x}) \quad (\text{C.9})$$

which can be easily checked by means of Eqs.(C.6) and (C.7);

- Both operators are of the Hilbert-Schmidt class because their integral kernels are square-integrable (the proof of this result is similar to the proof of the inequality (C.4); the starting point is the application of the Schwartz inequality to the r.h.s. of Eqs.(C.6) and (C.7));
- Both operators are positive semi-definite

$$(\bar{A}f, f)_{\mathcal{X}} \geq 0, \quad (\tilde{A}g, g)_{\mathcal{Y}} \geq 0. \quad (\text{C.10})$$

Remark C.1 *We sketch the proof of this property in the case of \bar{A} . Indeed, from Eq.(C.6), by means of an exchange of the integration order we have*

$$\begin{aligned} (\bar{A}f, f)_{\mathcal{X}} &= \int_{\Omega} \left(\int_{\Omega} \bar{K}(\mathbf{x}, \mathbf{x}')f(\mathbf{x}')d\mathbf{x}' \right) f^*(\mathbf{x})d\mathbf{x} \\ &= \int_{\Omega'} \left| \int_{\Omega} K(\mathbf{x}'', \mathbf{x})f(\mathbf{x})d\mathbf{x} \right|^2 d\mathbf{x}'' \geq 0. \end{aligned} \quad (\text{C.11})$$

A similar proof applies to the case of \tilde{A} . □

According to the Hilbert-Schmidt theory [Mi57], an integral operator with a symmetric and square-integrable kernel has real eigenvalues with finite multiplicity. Moreover the eigenfunctions associated with different eigenvalues are orthogonal. The eigenvalues form, in general, a countable set with zero as accumulation point.

If $\mathcal{K}(\mathbf{x}, \mathbf{x}')$ is a symmetric and square-integrable kernel, let $\lambda_1, \lambda_2, \lambda_3, \dots$ be the sequence of the eigenvalues of the corresponding integral operator, ordered in such a way that $|\lambda_1| \geq |\lambda_2| \geq |\lambda_3| \geq \dots$, each eigenvalue being counted as many times

as its multiplicity. Moreover, let $v_1(\mathbf{x}), v_2(\mathbf{x}), v_3(\mathbf{x}), \dots$ be the sequence of the eigenfunctions associated with these eigenvalues. They constitute an orthonormal set of square-integrable functions. Then the basic result of the Hilbert-Schmidt theory is the following *spectral representation* of the kernel $\mathcal{K}(\mathbf{x}, \mathbf{x}')$

$$\mathcal{K}(\mathbf{x}, \mathbf{x}') = \sum_{k=1}^{\infty} \lambda_k v_k(\mathbf{x}) v_k^*(\mathbf{x}'), \quad (\text{C.12})$$

the series being convergent in the sense of the L^2 -norm. Accordingly, the eigenvalues λ_k satisfy the following condition

$$\sum_{k=1}^{\infty} \lambda_k^2 < \infty. \quad (\text{C.13})$$

The result stated above apply to the operators \bar{A} and \tilde{A} , whose non-zero eigenvalues are positive because they are positive semi-definite operators. One can also show that the operators \bar{A} and \tilde{A} have the same eigenvalues with the same multiplicity.

Let us denote by σ_k^2 the positive eigenvalues of \bar{A} , with the ordering $\sigma_1^2 \geq \sigma_2^2 \geq \dots \geq \sigma_k^2 \geq \dots$ and $\sigma_k^2 \rightarrow 0$ for $k \rightarrow \infty$. Again each eigenvalue has been counted as many times as its multiplicity, which is certainly finite as follows from the Hilbert-Schmidt theory.

A normalised eigenfunction v_k is associated to each eigenvalue σ_k^2 and these eigenfunctions constitute an orthonormal system, i.e. $(v_k, v_j)_{\mathcal{X}} = \delta_{kj}$. Then, to each eigenfunction v_k of \bar{A} we can associate a function u_k in \mathcal{Y} defined by

$$u_k(\mathbf{x}) = \frac{1}{\sigma_k} (A v_k)(\mathbf{x}). \quad (\text{C.14})$$

Using the relation $\tilde{A}A = A\bar{A}$, which can be easily proved by an exchange of integration order in the definition of the integral kernels, we obtain

$$(\tilde{A}u_k)(\mathbf{x}) = \frac{1}{\sigma_k} (A\bar{A}v_k)(\mathbf{x}) = \sigma_k^2 \left(\frac{1}{\sigma_k} (A v_k)(\mathbf{x}) \right) = \sigma_k^2 u_k(\mathbf{x}) \quad (\text{C.15})$$

and also

$$\begin{aligned} (u_k, u_j)_{\mathcal{Y}} &= \frac{1}{\sigma_k \sigma_j} (A v_k, A v_j)_{\mathcal{Y}} \\ &= \frac{1}{\sigma_k \sigma_j} (v_k, \bar{A} v_j)_{\mathcal{X}} = \frac{\sigma_j}{\sigma_k} (v_k, v_j)_{\mathcal{X}} = \delta_{kj}. \end{aligned} \quad (\text{C.16})$$

Therefore all eigenvalues σ_k^2 of \bar{A} are also eigenvalues of \tilde{A} and the u_k are the corresponding eigenfunctions, which constitute an orthonormal system in \mathcal{Y} . In order to show that in this way we have obtained all eigenvalues and eigenfunctions of \tilde{A} it is sufficient to repeat the same argument starting from \tilde{A} . If its eigenvalues and

eigenfunctions are denoted by σ_k and u_k respectively, then we can show, by means of the relation $\bar{A}A^* = A^*\bar{A}$, that the functions of \mathcal{X} defined by

$$v_k(\mathbf{x}) = \frac{1}{\sigma_k}(A^*u_k)(\mathbf{x}) \quad (\text{C.17})$$

are orthonormal eigenfunctions of \bar{A} associated with the eigenvalues σ_k^2 .

Eqs.(C.14) and (C.17) define the usual shifted eigenvalue problem, which we write now explicitly in terms of the integral operators

$$\int_{\Omega} K(\mathbf{x}, \mathbf{x}')v_k(\mathbf{x}')d\mathbf{x}' = \sigma_k u_k(\mathbf{x}), \quad (\text{C.18})$$

$$\int_{\Omega'} K^*(\mathbf{x}, \mathbf{x}')u_k(\mathbf{x})d\mathbf{x} = \sigma_k v_k(\mathbf{x}'). \quad (\text{C.19})$$

The proof of the SVD of the operators A and A^* requires the completeness of the Hilbert spaces \mathcal{X} and \mathcal{Y} . We do not report this proof here (see, for instance, [Gr93]). We only give the result, which takes the form:

$$(Af)(\mathbf{x}) = \sum_{k=1}^{\infty} \sigma_k (f, v_k)_{\mathcal{X}} u_k(\mathbf{x}) \quad (\text{C.20})$$

and also

$$(A^*f)(\mathbf{x}) = \sum_{k=1}^{\infty} \sigma_k (g, u_k)_{\mathcal{Y}} v_k(\mathbf{x}), \quad (\text{C.21})$$

the series being convergent with respect to the norms of \mathcal{Y} and \mathcal{X} , respectively.

We also remark that the SVD of A is equivalent to the following series expansion of the kernel $K(\mathbf{x}, \mathbf{x}')$

$$K(\mathbf{x}, \mathbf{x}') = \sum_{k=1}^{\infty} \sigma_k u_k(\mathbf{x})v_k^*(\mathbf{x}'), \quad (\text{C.22})$$

the series being convergent with respect to the L^2 -norm. From this expansion (which is a generalisation of equation (C.12)), from the orthogonality of the singular functions and from the definition (C.2) of $\|K\|^2$ it follows that

$$\|K\|^2 = \sum_{k=1}^{\infty} \sigma_k^2 \quad (\text{C.23})$$

and therefore *the sum of squares of the singular values of a Hilbert-Schmidt integral operator is convergent.*

Using the SVD (C.20) it is also possible to show that the norm of the integral operator A is given by

$$\|A\| = \sigma_1. \quad (\text{C.24})$$

From this equation and (C.23), it follows that *the norm of the integral operator is never greater than the L^2 -norm of the integral kernel; the two norms coincide if and only if the integral operator has rank one.*

Statistics

In statistics we are interested in using a given sample of data to make inferences about a probabilistic model, e.g., to assess the model's validity or to determine the values of its parameters. There are two main approaches to statistical inference, which we may call frequentist and Bayesian. In frequentist statistics, probability is interpreted as the frequency of the outcome of a repeatable experiment. Note that in frequentist statistics one does not define a probability for a hypothesis or for a parameter.

Frequentist statistics provides the usual tools for reporting objectively the outcome of an experiment without needing to incorporate prior beliefs concerning the parameter being measured or the theory being tested.

In Bayesian statistics however, the interpretation of probability is more general and includes the notion of a “degree of belief”. One can then speak of a probability distribution function (p.d.f.) for a parameter, which expresses one's state of knowledge about where its true value lies. Bayesian methods allow for a natural way to include additional information such as physical boundaries and subjective information; in fact they *require* as input the *prior* p.d.f. for the parameters, i.e., the degree of belief about the parameters' values before carrying out the measurement.

Bayesian techniques are often used to treat systematic uncertainties, where the subjective beliefs about, say, the accuracy of the measuring device may enter. Bayesian statistics also provides a useful framework for discussing the validity of different theoretical interpretations of the data.

For many inference problems, the frequentist and Bayesian approaches give the same numerical answers, even though they are based on fundamentally different interpretations of probability. For small data samples, however, and for measurements of a parameter near a physical boundary, the different approaches may yield different results, so we are forced to make a choice. For a discussion of Bayesian vs. non-Bayesian methods, see references written by a statistician [Ef86], by a physicist [Co95], or the more detailed comparison in Ref.[SOA98].

In what follows we will concentrate on frequentist statistics and briefly discuss least-squares parameter estimation, confidence regions and the χ^2 test of goodness-of-fit. In Chapters 5, 6 and 7 we aimed to determine values of some fundamental QCD parameters, the so called condensates, in a least-squares sense. The errors on these parameters were then defined through constant χ^2 boundaries as CLs around the values found. It was also important to define the level of agreement between data and theory, for which we have made use of the χ^2 test.

D.1 Least-squares parameter estimation

Consider a situation in which N data pairs, x_i, y_i , with $i = 1, 2, \dots, N$, are to be modeled by a functional relationship

$$F(\mathbf{x}) = F(\mathbf{x}, \boldsymbol{\theta}), \quad y_i = F(x_i, \boldsymbol{\theta}), \quad (\text{D.1})$$

where $\boldsymbol{\theta}$ is the vector of M adjustable parameters θ_j . The goal is to determine the “best” values of $\boldsymbol{\theta}$ that describe the true values $\boldsymbol{\theta}_0$.

Given a particular data set of x_i 's and y_i 's, we have the intuitive feeling that some parameters $\boldsymbol{\theta}$ are very unlikely (those for which the model function $F(\mathbf{x})$ looks *nothing like* the data) while others may be very likely (those that closely resemble the data). How can we quantify this intuitive feeling? How can we select fitted parameters that are *most likely* to be correct? It is not meaningful to ask the question, “What is the probability that a particular set of fitted parameters $\boldsymbol{\theta}$ is correct?” The reason is that there is no statistical universe of models from which the parameters are drawn. There is just one model, the correct one, and a statistical universe of data sets that are drawn from it.

That being the case, we can, however, turn the question around, and ask, “Given a particular set of parameters, what is the probability that this data set could have occurred?” If the y_i 's take on continuous values, the probability will always be zero unless we add the phrase, “...plus or minus some fixed Δy on each data point”. So let's always take this phrase as understood. If the probability of obtaining the data set is infinitesimally small, then we can conclude that the parameters under consideration are *unlikely* to be right. Conversely, our intuition tells us that the data set should not be too improbable for the correct choice of parameters.

In other words, we identify the probability of the data given the parameters as the *likelihood* of the parameters given the data. This identification is entirely based on intuition. It has no formal mathematical basis in and of itself. Once we made this intuitive identification, however, it is only a small further step to decide to fit for the parameters $\boldsymbol{\theta}$ precisely by finding those values that *maximise* the likelihood defined in the above way.

Suppose that each data point y_i has a measurement error σ_i and that y_i are independently random and distributed as a normal (Gaussian) distribution around the *true* model $F(\mathbf{x})$. Then the probability P that the data set is described by $F(\mathbf{x})$ is given by

$$-\ln P \propto \chi^2(\boldsymbol{\theta}) = \sum_{i=1}^N \left(\frac{y_i - F(x_i; \boldsymbol{\theta})}{\sigma_i} \right)^2. \quad (\text{D.2})$$

Maximising the joint probability function, P , is equivalent to minimising χ^2 . This is achieved by differentiating Eq.(D.2) for each θ_j

$$\frac{\partial \chi^2}{\partial \theta_j} = -2 \sum_{i=1}^N \left(\frac{y_i - F(x_i; \boldsymbol{\theta})}{\sigma_i^2} \right) \left(\frac{\partial F(x_i; \boldsymbol{\theta})}{\partial \theta_j} \right), \quad (\text{D.3})$$

and equating to zero. Obtaining Eq.(D.3) for each j yields a set of M equations, one for each unknown θ_j . Minimising χ^2 thus reduces to solving a system of M equations.

The curvature matrix

$$\alpha_{jk} = \frac{1}{2} \frac{\partial^2 \chi^2}{\partial \theta_j \partial \theta_k} = \sum_{i=1}^N \frac{1}{\sigma_i^2} \left[\frac{\partial F(x_i; \boldsymbol{\theta})}{\partial \theta_j} \frac{\partial F(x_i; \boldsymbol{\theta})}{\partial \theta_k} \right], \quad (\text{D.4})$$

defines the covariance matrix for the parameters:

$$V = \alpha^{-1}. \quad (\text{D.5})$$

Once χ^2 is minimised, the variances in the parameters $\boldsymbol{\theta}$ are approximated by the diagonal matrix elements of V :

$$\sigma_{\theta_j}^2 = V_{jj}. \quad (\text{D.6})$$

D.2 Confidence regions

The full probability distribution is a function defined on the M -dimensional space of parameters $\boldsymbol{\theta}$. A *confidence region* (or *confidence interval*) is just a region of that M -dimensional space that contains a certain percentage of the total probability distribution. When pointing to a confidence region one can say, e.g., “this is a 99% chance that the measured values y_i are obtained from the model with the parameter values $\boldsymbol{\theta}$ lying within this region”.

It is worth emphasising that one has to determine both the *confidence level* (99% in the above example), and the shape of the confidence region. The only requirement is that the region does include the stated percentage of probability. Certain percentages are, however, customary in scientific usage: 68.27% (the lowest confidence worthy of quoting) also called 1σ CL, 90%, 95.45% (2σ CL), 99% and 99.73% (3σ CL). Higher CL’s are conventionally “ninety-nine point nine ... nine”. As for shape, obviously one wants a region that is compact and reasonably centred on $\boldsymbol{\theta}_0$, since the whole purpose of a confidence limit is to inspire confidence in that value. In one dimension, the convention is to use a line segment centred on the measured value; in higher dimensions, ellipses or ellipsoids are most frequently used.

The numbers 68.27%, 95.45% and 99.73% and the use of ellipsoids are connected with a Gaussian distribution, however not always relevant. In general, the probability distribution of the parameters will not be Gaussian, and the above numbers, used as levels of confidence, are purely matters of convention. In these cases, the simple quotation of error ranges like $\boldsymbol{\theta}_0 \pm \Delta\boldsymbol{\theta}$ do not provide information about the shape of the p.d.f.

Fig.D.1 sketches a possible probability distribution for the case $M = 2$. Shown are three different confidence regions, all at the same confidence level. The two vertical lines enclose a band (horizontal interval) which represents the 1σ CR for the variable θ_1 without regard to the value of θ_2 . Similarly the horizontal lines enclose a 1σ CR for θ_2 . The ellipse shows a joint 1σ CR for pairs of values θ_1 and θ_2 .

Figure D.1: Confidence intervals in 1 and 2 dimensions. The same fraction of measured points (here 68.27%) lies (i) between the two vertical lines, (ii) between the two horizontal lines, (iii) within the ellipse.

D.3 Constant χ^2 boundaries as CL

When the method used to estimate the parameters is χ^2 -minimisation, as in Section D.1, then there is a natural choice for the shape of confidence intervals, whose use is almost universal. For the observed data, the value of χ^2 at $\boldsymbol{\theta}_0$ is a minimum. Call this minimum χ_{\min}^2 . If the vector $\boldsymbol{\theta}$ of parameter values is perturbed away from $\boldsymbol{\theta}_0$, then χ^2 increases. The region within which χ^2 increases by no more than a chosen amount $\Delta\chi^2$ defines some M -dimensional confidence region around $\boldsymbol{\theta}_0$. If $\Delta\chi^2$ is set to be a large number, this will be a big region; if it is small, it will be small. Somewhere in between there will be choices of $\Delta\chi^2$ that cause the region to contain, variously, 1σ , 2σ , etc. of probability distributions for $\boldsymbol{\theta}$, as defined above. These regions are taken as the confidence regions for the parameters $\boldsymbol{\theta}_0$. Values of $\Delta\chi^2$ for different confidence regions and different numbers of parameters are listed in Table D.1.

Very frequently one is interested not in the full M -dimensional confidence region, but in individual confidence regions for some smaller number ν of parameters. For example, one might be interested in the confidence interval of each parameter taken separately (the bands in Fig.D.1), in which case $\nu = 1$. In that case, the natural confidence regions in the ν -dimensional subspace of the M -dimensional parameter space are the *projections* of the M -dimensional regions defined by fixed $\Delta\chi^2$ into the ν -dimensional spaces of interest.

CR(%)	$M = 1$	$M = 2$	$M = 3$
68.27	1.00	2.30	3.53
90.00	2.71	4.61	6.25
95.45	4.00	6.18	8.03
99.00	6.63	9.21	11.34
99.73	9.00	11.83	14.16

Table D.1: $\Delta\chi^2$ corresponding to a confidence region CR, for joint estimation of M parameters based on Gaussian (normal) p.d.f.

D.4 The χ^2 test

'Don't ask what it means, but rather how it is used.'

L. Wittgenstein

Often one wants to quantify the level of agreement between the data and a hypothesis without explicit reference to alternative hypotheses. This can, in many cases, be done by the χ^2 test invented in 1900 by Karl Pearson [Pe1900].

The goodness-of-fit is quantified by giving the *observed significance level* also called p -value. The p -value is defined as the probability to find χ^2 in the region of equal or smaller compatibility with the considered hypothesis than the level of compatibility observed with the actual data. Since χ^2 is defined such that large values correspond to poor agreement with the hypothesis, the p -value will be

$$p = \int_{\chi^2}^{\infty} f(z; n) dz \quad (\text{D.7})$$

where χ^2 is the value obtained in the minimisation process (e.g., in the present work the value of $\chi_{L,\min}^2$, Eq.(5.10), was used to estimate the agreement between experimental data and the theoretical model, i.e., QCD). $f(z; n)$ is the χ^2 p.d.f. with n degrees of freedom¹,

$$f(z; n) = \frac{1}{\Gamma(n/2)2^{n/2}} z^{n/2-1} e^{-z/2}, \quad (\text{D.8})$$

where $z \geq 0$ and $f(z; n) = 0$ for $z \leq 0$. Here Γ denotes the Gamma function.

Values of p can be obtained from Fig.D.2. If the conditions for using the χ^2 p.d.f. do not hold, the p -value can still be defined as before, but the p.d.f., f , must be determined by other means, e.g., using a Monte Carlo calculation.

¹The term *degrees of freedom* is a measure of the number of independent pieces of information on which the precision of a parameter estimate is based. The degrees of freedom for an estimate equals the number of observations (values) minus the number of additional parameters estimated for that calculation. As we have to estimate more parameters, the degrees of freedom available decreases. It can also be thought of as the number of observations (values) which are freely available to vary given the additional parameters estimated.

If one finds a χ^2 value much greater than n and a correspondingly small p -value, one may be tempted to expect a high degree of uncertainty for any fitted parameter. Although this may be true for systematic errors in the parameters, it is not in general the case for statistical uncertainties. If, for example, the error bars (or covariance matrix) used in constructing the χ^2 are underestimated, then this will lead to underestimated statistical errors for the fitted parameters. But in such a case an estimate θ_0 can differ from the true value θ by an amount much greater than its estimated statistical error. The standard deviations of estimators that one finds reflect how widely the estimates would be distributed as if one were to repeat the measurement many times, assuming that the measurement errors used in χ^2 are also correct. They do not include the systematic error which may result from an incorrect hypothesis or incorrectly estimated measurements errors in the χ^2 .

Since the mean of the χ^2 distribution is equal to n , one expects in a “reasonable” experiment to obtain $\chi^2 \approx n$. Hence the quantity χ^2/n is sometimes reported. Since the probability distribution function of χ^2/n depends on n , however, one must report n as well in order to make a meaningful statement. The p -values obtained for different values of χ^2/n are shown in Fig.D.3.

Figure D.2: The p -value as a function of χ^2 for n degrees of freedom.

Figure D.3: The “reduced” χ^2 , equal to χ^2/n , for n degrees of freedom. The curves show χ^2/n that corresponds to a given p -value as a function of n .

Curriculum vitae

Personal details

<i>Name</i>	Andrea Amalia Almasy
<i>Postal address</i>	Institut für Physik, WA ThEP Johannes Gutenberg Universität 55099 Mainz
<i>Date of birth</i>	4 February 1980, Sighetu Marmăției, Romania
<i>Nationality</i>	Romanian

Education

June 1998	Scientific baccalaureate, Dragoș Vodă High School, Sighetu Marmăției, Romania
June 1998	Diploma of <i>Programming assistant</i>
1998-2002	Student at the Physics Faculty, University of Bucharest, Romania
June 2002	B.Sc. in Theoretical Physics, University of Bucharest, Romania
Sept-Dec 02	Erasmus research period at University Montpellier II, France
Feb 2006	M.Sc. in Theoretical Physics, University of Bucharest, Romania
since Oct 03	Ph.D. student, Institut für Physik, Johannes Gutenberg Universität Mainz
