Statutory Declaration

I herewith declare that I have composed the present thesis myself and without the use of any other than the cited sources and aids. Sentences or parts of sentences quoted literally are marked as such; other references with regards to the statement and scope are indicated by full details of the publications concerned. The thesis in the same or similar form has not been submitted to any examination body and has not been published.

Place, Date: _____

Signature: _____

Acknowledgments

Abstract

The mammalian brain is a remarkably complex organ whose development relies on precise molecular and cellular processes. One of the most sophisticated brain structures is the cerebral cortex. Many proteins and microRNAs play distinct roles in the posttranscriptional regulation of corticogenesis. Mutations in RNA-binding proteins and miRNAs are linked to neurodevelopmental disorders, highlighting their crucial role in central nervous system development.

This doctoral thesis investigates posttranscriptional mechanisms that shape brain development, focusing on alternative splicing and microRNA regulation. Premature overexpression of the RNA binding protein *Rbfox2* during murine corticogenesis caused migration and differentiation defects through an altered splicing pattern, likely antagonizing PTBP2's splicing program. In this study, it was further shown that the neuronal progenitor cell-specific miR-92a-3p repressed *Rbfox2* both *in vitro* and *in vivo*, revealing a novel regulatory relationship between miRNAs and splicing factors during neural development.

Furthermore, analysis of miRNAs during embryonic corticogenesis revealed clusters of coregulated miRNAs with overlapping target sets. Luciferase assays showed that such cotargeting of miRNAs enhances the repression effect on shared target mRNAs. This finding suggests a complex regulatory network where multiple miRNAs cooperatively fine-tune gene expression during brain development.

To support future research, two computational tools were developed: a web portal (www.cortexa-rna.com) providing access to neocortex/hippocampus RNA-sequencing datasets, improving the accessibility of transcriptomic data to the broader scientific community. Additionally, I implemented a deep learning framework for denoising functional imaging recordings. This computational tool enables the validation of molecular changes in synaptic function at single synapse resolution, bridging the gap between molecular alterations (including splicing-induced changes) and their functional consequences in neurons.

Zusammenfassung

Das Gehirn von Säugetieren ist ein komplexes Organ, dessen Entwicklung von präzisen molekularen und zellulären Prozessen abhängt. Eine der komplexesten Gehirnstrukturen ist der Kortex. Mehrere Proteine und microRNAs spielen bei der posttranskriptionellen Regulierung der Kortikogenese eine besondere Rolle. Mutationen in RNA-bindenden Proteinen und microRNAs werden mit neurologischen Entwicklungsstörungen in Verbindung gebracht, was ihre entscheidende Rolle bei der Entwicklung des zentralen Nervensystems unterstreicht.

Diese Doktorarbeit untersuchte posttranskriptionale Mechanismen, welche die Entwicklung des Gehirns beeinflussen, und fokussiert sich dabei auf alternatives Spleißen und die Regulierung von microRNAs. Die vorzeitige Überexpression des RNA-bindenden Proteins *Rbfox2* während der Kortikogenese bei Mäusen verursachte Migrations- und Differenzierungsdefekte durch ein verändertes Spleißmuster, das wahrscheinlich das Spleißprogramm von PTBP2 antagonisiert. Diese Studie konnte außerdem zeigen, dass die für neuronale Vorläuferzellen spezifische miR-92a-3p *Rbfox2* sowohl *in vitro* als auch *in vivo* unterdrückt, was eine neuartige regulatorische Beziehung zwischen miRNAs und Spleißfaktoren während der neuralen Entwicklung aufzeigt.

Darüber hinaus ergab die Analyse der miRNAs während der embryonalen Kortikogenese Cluster koregulierter miRNAs mit sich überschneidenden Zielgruppen. Luziferase-Assays konnten zeigen, dass eine solche gemeinsame Ausrichtung von miRNAs die Unterdrückungswirkung auf gemeinsame Ziel-mRNAs verstärkt. Dieses Ergebnis deutet auf ein komplexes regulatorisches Netzwerk hin, in dem mehrere miRNAs die Genexpression während der Gehirnentwicklung gemeinsam feinabstimmen.

Zur Unterstützung künftiger Forschung wurden zwei Tools entwickelt: ein Webportal (www.cortexa-rna.com), das Zugang zu RNA-Sequenzierungsdatensätzen von Neokortex und Hippocampus bietet und die Zugänglichkeit transkriptomischer Daten für eine breitere wissenschaftliche Gemeinschaft verbessert. Darüber hinaus habe ich einen Deep-Learning-Framework für die Unterdrückung von Rauschen in funktionellen Mikroskopieaufnahmen implementiert. Dieses Tool ermöglicht die Validierung von

durch Spleißen induzierten Veränderungen der synaptischen Funktion und ermöglicht somit in einzelnen Synapsen molekularen Veränderungen auf ihre funktionellen Konsequenzen hin zu untersuchen.

Genes associated with the GO term **alternative mRNA splicing via the spliceosome** (GO:0000380) were selected and further filtered for base expression > 100 and differential regulation between E14 and P0, resulting in a list of 43 genes. Due to their known involvement in cortical development, *Rbfox2*³⁵ and *Ptbp2*²⁷ were manually added to this list. **a** Heatmap depicting the log₂ transformed transcripts per

million (TPM) expression values for the differentially expressed splicing-associated proteins during cortical development. Original data from left to right: FACS-sorted NPCs and neurons of the cerebral cortex³¹, Developmental data of the cerebral cortex³⁶, FACS-sorted neuronal cells in the cortex and hippocampus²³. Processed data were obtained from the web portal Cortexa³⁷. **b** Principal component analysis based on the expression values of the selected genes involved in splicing during development. The variance is mainly captured by PC1 (~80 %). The direction of development is indicated by arrows. **c** Principal component analysis for the selected genes in the mature cortex and hippocampus for specific neuronal cell types. Excitatory and inhibitory neurons are separated by PC1, which accounts for a majority of the variance (~34 %). PC2 separates *Vip*-positive neurons from other inhibitory neurons.23

Figure 6 Principal component analysis of skipping exon events in the developing cortex and distinct neuronal cell types in the adult cortex and hippocampus. The developmental data are separated from left (E14) to right (P30) along the first principal component and show a bell-shaped curve with a peak at birth (P0). The different excitatory cell types (all mature cells) in the cortex and hippocampus are grouped into one small cluster (marked with an orange, dashed circle), while the inhibitory neurons form a looser cluster (marked with a blue, dashed ellipse). Data were analyzed and obtained from the web portal Cortexa³⁷.25

Figure 7 a Schematic representation of RBFOX protein functions: alternative splicing regulation, mature mRNA stability control, inhibition of miRNA biogenesis, and protein-protein interactions. **b** Heatmap showing expression levels of RBFOX1, RBFOX2, and RBFOX3 across various human tissues and cell types. Data from human protein atlas⁶⁶ **c** Phylogenetic analysis of RBFOX paralogs in *Mus musculus*. The canonical protein sequences were obtained from UniProt and aligned using the Clusta algorithm. Afterward, the phylogenetic tree was constructed using the neighbor-joining method within the MegaX software⁶⁷. **d** Expression pattern of *Rbfox1-3* in NPCs/neurons (E14)⁶⁸, throughout development (E14-P30) in the neocortex⁸, and in mature neocortical/hippocampal neurons sorted according to marker genes²³. Data were obtained from the web portal Cortexa³⁷. **e** Regulatory mechanisms ensuring precise RBFOX levels: regulatory feedback loop of RBFOX1 and RBFOX2, RBFOX3 induced

NMD of *Rbfox2*, splicing of the RRM to reduce the binding affinity of RBFOX, miRNA suppression, and sequestering.29

Figure 8 Canonical miRNA biogenesis pathway. The pri-miRNA is cleaved by a protein complex consisting of Drosha and two DGCRB proteins. The resulting pre-miRNA is exported through Exportin 5 into the cytoplasm. Dicer removes the loop, and subsequently, the mature miRNA can bind together with Ago 1-4 to the target mRNA's UTR. Figure modeled after Shang et al., 2023⁷⁶32

Figure 9 Regulatory effect of microRNAs during cortical development **a** Heatmap on the left shows the expression of known relevant miRNAs during the development of the neocortex⁷ and miR-92a³⁸ at time points E14, E17, and P0⁴⁷; the heatmap on the right shows the expression of validated developmentally important miRNA targets⁸. Expression was normalized to the maximum value for E14, E16/E17, and P0 of the respective miRNA/gene. **b** Developmental GO terms of the targets regulated by the respective miRNAs, according to Lennox et al., 2018⁷. **c** Principal component analysis of microRNA expression during neocortical development³⁸. The main variance is encoded on PC1 (92.18 %), and E14 is separated from the two later stages, E17 and P0. **d** Principal component analysis of cell-specific miRNA expression in the neocortex for the inhibitory neurons Sst, Vip, pan-inhibitory Gad2-positive neurons, and excitatory Camk2a neurons⁷⁸. **e** Schematic representation of the PTBP1/PTBP2 switch during neural differentiation. PTBP1 induces the inclusion of a poison exon into the pre-mRNA of *Ptbp2*, and the resulting mRNA is subsequently degraded by NMD. By the expression of miR-124-3p, *Ptbp1* is degraded, and thus, the poison exon in *Ptbp2* is not included⁴⁵. Therefore, the expression of PTBP1 and PTBP2 is mutually exclusive⁶⁵.34

Figure 10 Regulatory mechanisms of microRNA biogenesis and processing **a** Protein-Protein interaction: DGCR8 forms a complex with Drosha in the microprocessor. **b** Transcriptional repression: The DGCR8-DROSHA complex binds to and cleaves *Dgcr8* mRNA, regulating its expression. **c** Protein modifications: Posttranslational modifications of DGCR8, including acetylation, TDP43 binding, and deacetylation. Phosphorylation of DGCR8 leads to sequestration by MECP2, affecting neuronal activity. **d** Dicer/let-7 feedback loop: lack of Dicer leads to reduced miRNAs and increased let-7 expression. Let-7 targets Dicer mRNA, creating a regulatory feedback loop. **e** Dicer/let-7 feedback loop interference: Lin-28 blocks the processing of pre-let-

7, interfering with the feedback mechanism. **f** Dicer mRNA processing: Exp5 inhibits Dicer mRNA processing, resulting in accumulation of excess pre-miRNAs in the nucleus and reduced mature miRNA production.36

Figure 11 Illustration depicting the effects of *Rbfox2* overexpression on cerebral cortex development. **a** normal development, showing the typical layered structure from the ventricular zone (VZ) at the bottom to the cortical plate (CP) at the top. Neural progenitor cells (NPCs) in the VZ give rise to radial glial cells that span the developing cortex. Intermediate progenitor cells in the subventricular and intermediate zones (SVZ/IZ) produce neurons that migrate along radial glia to form the cortical layers. **b** Alterations caused by *Rbfox2* overexpression, leading to a reduction in neurons reaching the cortical plate (migration defect) and an increase in NPC and intermediate progenitor cells in the SVZ/IZ (differentiation defect).160

1 Introduction

Brain development is a complex process that begins during early embryogenesis and continues well into adulthood. Forming specialized brain regions involves the precise orchestration of cell proliferation, migration, and differentiation into diverse neural cell types. Among brain regions, the cerebral cortex has emerged as one of the most evolutionarily advanced structures, responsible for higher-order processing and cognitive capabilities¹. The cerebral cortex forms the outermost layer of the cerebral hemispheres and harbors a wide variety of specialized cells ranging from auxiliary cells (e.g., glial cells) to highly specialized neurons. It controls cognitive functions such as thought and language in mammals, enabling complex behavior. The neocortex, which represents the largest and most evolutionarily advanced component of the cerebral cortex², is structured in six layers composed of different neurons. Most neurons are excitatory, pyramidal-projection neurons (75-85 %). The remaining 15-25 % can be attributed to inhibitory GABAergic interneurons. The composition of inhibitory and excitatory neurons in the cerebral cortex differs among mammalian species³.

In *Mus musculus*, a widely used model organism for investigating mammalian physiology and development (**Figure 1**), corticogenesis is initiated mid-gastrulation between embryonic days 9 and 10 (E9–E10)⁴. In this early phase, the pool of neural progenitor cells (NPCs) in the form of neuroepithelial cells expands through symmetric divisions. Gradually, neuroepithelial cells transform into radial glial cells (RGCs), the main type of NPC. Most RGCs are attached to the ventricular surface and are multipotent cells. Thus, they can differentiate into different types of neural cells, e.g., neurons, astrocytes, or oligodendrocytes, by asymmetric divisions. In asymmetric divisions, a radial glial cell divides to produce two distinct daughter cells: one that retains the properties of the parent cell (self-renewal) and another that becomes a more differentiated cell type⁵. The fate of the differentiating daughter cell is determined by the precise temporal competence of the parent cell and the influence of various intrinsic and extrinsic factors at the time of division⁴. Once generated, newborn neurons migrate radially from the ventricular zone toward the cortical plate, using the basal processes of radial glial cells as scaffolds⁵. This migration occurs in an inside-out pattern, with earlier-born neurons forming the deeper layers of the cortex and later-born neurons migrating past them to form the upper layers. This process results in the formation of

the characteristic six-layered structure of the mammalian neocortex, with each layer containing neurons with distinct molecular identities and functional properties⁶.

Figure 1 Spatiotemporal progression of murine cerebral cortex development inspired by Koo et al., 2023⁴. The schematic illustration depicts the key stages and cell types involved in the development of the mouse cerebral cortex from early embryonic day 9 (E9) through postnatal stages. The figure shows the transformation of the neuroepithelium into a complex, layered structure. E9 - E11: Neuroepithelial cells (NECs) in the ventricular zone (VZ). At E11 - E14, NECs transform into radial glial cells (RGCs), which span from the VZ to the pial surface. E14 - E17: RGCs produce neurons directly or via intermediate progenitor cells (IPCs) in the subventricular zone (SVZ). Neurons migrate along RGC processes. E17-Postnatal: Cortical layers form in an inside-out pattern, creating a mature structure: the VZ, SVZ, intermediate zone (IZ), cortical plate (CP), and marginal zone (MZ).

Underlying these complex processes of asymmetric division, fate determination, and neuronal migration is a regulatory framework that extends beyond transcriptional control. During cortical development, extensive changes occur in the posttranscriptional landscape (**Figure 2**), playing a crucial role in shaping the neurogenic process. These modifications go beyond mere gene expression and involve complex regulatory mechanisms that fine-tune the production, processing, and stability of RNA molecules. Among the most prominent posttranscriptional regulatory mechanisms that are studied in the context of CNS development are alternative splicing and gene translation suppression through microRNA (miRNA) binding (**Figure 2**)^{7,8}. Recent technological advancements, such as direct RNA sequencing, most prominently using nanopore technology, have shed light on additional regulatory mechanisms that are gaining increasing attention in the research community. These

include dynamic changes in 3' untranslated region (3'-UTR) length through alternative polyadenylation, which can significantly impact RNA stability⁹. Furthermore, various RNA modifications have emerged as important factors in posttranscriptional regulation (**Figure 2**). These mechanisms provide an extra layer of control over gene expression, allowing for fine-tuned regulation of cellular processes during development¹⁰.

Figure 2 Key mechanisms of RNA regulation. The schematic shows RNA processing steps from transcription through nuclear export to cytoplasmic events including miRNA-mediated regulation, transport, translation, and degradation. Nuclear processes include RNA modification, splicing, and polyadenylation. The nuclear membrane (vertical line) separates nuclear and cytoplasmic events.

1.1 Alternative splicing

Although the genome of the mouse has approximately 22,000 protein-coding genes¹¹ that are shared among all cells, the mammalian brain exhibits a remarkable

transcriptomic diversity. As described by the Allen Brain Institute¹², as many as 388 transcriptomic cell types have been characterized in the cortex and hippocampus. This diversity is achieved partly by the process of alternative splicing (AS). Nearly every multi-exon gene in mammals undergoes alternative splicing¹³. Failures in alternative splicing can be linked to several neurological developmental disorders, highlighting its relevance for proper brain development¹⁴.

After a gene is transcribed into premature mRNA, the introns are removed from the sequence, and the exons are joined together into the mature mRNA¹⁵. The process of constitutive splicing is catalyzed by a large ribonucleotide complex called the spliceosome. The spliceosome assembles over introns or exons, respectively, and thus recognizes the boundaries of an exon¹⁶. Alternative splicing is a deviation from constitutive splicing, and therefore, individual exons of a gene may be included or excluded from the mature messenger RNA (mRNA)¹⁷. Exons are joined in different combinations, leading to differing mRNA transcripts (**Figure 3**). Proteins translated from alternatively spliced mRNAs usually exhibit differences in their amino acid sequence and, often, in their biological functions and structure¹⁷.

Moreover, alternative splicing not only shapes protein diversity but also exerts regulatory control over gene expression. By the inclusion of short exons that introduce a premature stop codon, so-called poison exons, the mRNA is degraded through the process of nonsense-mediated decay. Notably, one-third of all annotated transcripts include a premature stop codon¹⁸, highlighting the prevalence of this regulatory mechanism.

Figure 3 Simplified schematic of the process of alternative splicing. The gene, consisting of exons and introns, is read from the DNA into mRNA (transcription). In proximity to the exons, specific RBP binding sites (short sequences recognized by the

RBP) are present. RBPs regulate the process of alternative splicing, which is the alternative use of exons. Finally, the alternatively spliced mature mRNAs are processed into proteins with different structures (through translation). RBP: RNA binding protein.

There are different alternative splicing events known; in this thesis, the definition used within the rMATS software will be used (**Figure 4**)¹⁹. Thus, alternative splicing events include skipping exons (often referred to as cassette exons), mutually exclusive exons, intron retention, A5' alternative splice sites, and A3' alternative splice sites, as depicted in **Figure 4**. Skipping exons are the most common alternative splicing event, accounting for 73.2 % of all annotated splicing events in mm39. A mutually exclusive exon is an event with a group of two exons in which exactly one is spliced in, while the other is spliced out. Retained intron alternative splicing involves the inclusion of an intronic sequence in the mature mRNA. Finally, there are alternative A5' and A3' splice sites that lead to exons of varying length.

Figure 4 Different types of splicing events: skipping of exons, mutually exclusive exons, retained introns, alternative A5' splice sites, and alternative A3' splice sites.

1.1.1 Alternative splicing is guided by RNA-binding proteins

The assembly of the spliceosome can be altered by auxiliary proteins that bind to pre-mRNAs, so-called RNA binding proteins. RBPs are a diverse set of proteins that possess preferred binding motifs located in intronic or exonic mRNA sequences (**Figure 3**)¹⁶. The class of RBPs comprises over 2,000 known proteins that can interact with RNA in various ways²⁰. Many RBPs induce splicing changes upon binding to their

binding motif(s) on pre-mRNAs. The binding motifs of RBPs are relatively short, e.g., the four nucleotide sequence YCAY¹ to which NOVA2 binds²¹. These short sequences are referred to as RNA recognition motifs (RRMs). In general, RBPs regulate between 200 and 1,000 exons⁸. Despite the conserved RRM shared by paralogous RBPs within families, such as the RBFOX family, there is notable redundancy in their functions. The RBFOX family, for instance, comprises three paralogs with a common (U)GCAUG RRM, exhibiting significant overlap in their target sets²². Intriguingly, these paralogs display distinct expression patterns across various developmental stages, tissues, and cell types (**Figure 5**)^{8,23}. The reasons for this redundancy remain poorly understood.

Many RNA-binding proteins exert position-dependent splicing changes, where upstream binding relative to a regulated exon leads to repression and downstream binding to the inclusion of the exon. This position-dependent effect has been reported for multiple RBPs involved in cortical development, such as RBFOX^{22,24}, NOVA²⁵, and MBNL²⁶. However, a notable exception is the PTBP family, whose member proteins mostly bind upstream of regulated exons²⁷ and cause exon repression.

1.1.2 Alternative splicing in developing and mature tissues

Several splicing changes are required for key processes during embryonic brain development, such as cell proliferation⁷, neuronal differentiation²⁸, and neuronal migration^{21,29}, among others. Moreover, cell-type-specific transcripts have a vast impact on the functionality of the resulting proteins, as exemplified by the vSNARE protein VAMP1, which is specifically expressed in inhibitory neurons. Its expression is regulated by the RNA-binding protein RBFOX1, and disruption of this regulation leads to decreased inhibitory synaptic transmission, highlighting the importance of neuron-specific transcript regulation³⁰. Splicing switches are mainly driven by regulatory RBPs, and they must occur with high temporal precision⁸. The expression of RBPs is, therefore, tightly controlled and specific to developmental stages (**Figure 5a** left and middle, **Figure 5b**) and cell types (**Figure 5a** right, **Figure 5c**)^{8,23,31}. For instance, several RNA-binding proteins are sequentially expressed, especially during cortical

¹ Y represents a pyrimidine (cytosine or uracil)

development (**Figure 5a** left and middle). Interestingly, the reduced representation of global expression of RBPs related to alternative splicing in two-dimensional space reveals a bell-shaped trajectory which is typically observed for multiple brain developmental processes (**Figure 5b**). Though the transition from pre- to post-natal stages accounts for the highest amount of variance, P0 emerges as an inflection point in this developmental trajectory indicating a shift in the expression direction of RBPs postnatally compared to embryonic stages.

Alternative splicing also plays an important role in adult cells and neurons^{13,29,32,33} and mature cortical and hippocampal cells differ based on the expression signature of RBPs (**Figure 5c**). While excitatory neurons cluster together, the group of inhibitory neurons is more diverse. *Vip-* and *Parvalbumin*-positive inhibitory neurons are distinct from all other neuronal subtypes, revealing a more complex splicing-associated protein composition for inhibitory compared to excitatory neurons. Consequently, the presence or absence of distinct RBPs can mediate cell-type specific alternative splicing³⁴.

Figure 5 Differentially expressed alternative splicing-associated genes during cortical development. Genes associated with the GO term **alternative mRNA splicing via the spliceosome** (GO:0000380) were selected and further filtered for base expression > 100 and differential regulation between E14 and P0, resulting in a

list of 43 genes. Due to their known involvement in cortical development, *Rbfox2*³⁵ and *Ptbp2*²⁷ were manually added to this list. **a** Heatmap depicting the log₂ transformed transcripts per million (TPM) expression values for the differentially expressed splicing-associated proteins during cortical development. Original data from left to right: FACS-sorted NPCs and neurons of the cerebral cortex³¹, Developmental data of the cerebral cortex³⁶, FACS-sorted neuronal cells in the cortex and hippocampus²³. Processed data were obtained from the web portal Cortexa³⁷. **b** Principal component analysis based on the expression values of the selected genes involved in splicing during development. The variance is mainly captured by PC1 (~80 %). The direction of development is indicated by arrows. **c** Principal component analysis for the selected genes in the mature cortex and hippocampus for specific neuronal cell types. Excitatory and inhibitory neurons are separated by PC1, which accounts for a majority of the variance (~34 %). PC2 separates *Vip*-positive neurons from other inhibitory neurons.

Global splicing changes that occur during development and the differences between distinct neuronal subtypes can be represented using principal component analysis^{8,37,38}. This integrative data analysis method reveals that alternative splicing gradually changes throughout the development of the cerebral cortex. Typically, the main axis of variation is encompassed by principal component 1, which captures the changes in the splicing pattern of embryonic day 14 to postnatal day 30 (**Figure 6**). The inferred developmental trajectory shows a typical bell shape, peaking at the day of birth of (P0) as previously observed^{8,37,38}. Intriguingly, splicing patterns remain robust to batch effects even when data from fluorescence-activated cell-sorted (FACS) mature neurons²³ are integrated. In contrast, gene expression studies³⁹ are particularly affected by biases from different sequencers and bioinformatic pipelines⁴⁰.

Distinct splicing patterns are also attributable to different types of differentiated cells in the brain (**Figure 6**). CamK2-positive, Grik4-positive, and Scnn1a-positive excitatory neurons form a tight cluster that is closely located to P30 bulk cortical samples in reduced dimensional space. Inhibitory neurons form a less homogenous cluster whose global splicing pattern differs from the remaining samples. Strikingly, although these cells were extracted from the hippocampus or cerebral cortex, inhibitory neurons do not develop within these structures but migrate from three distinct regions of the subpallium: the medial and caudal ganglionic eminences and the preoptic area⁴¹.

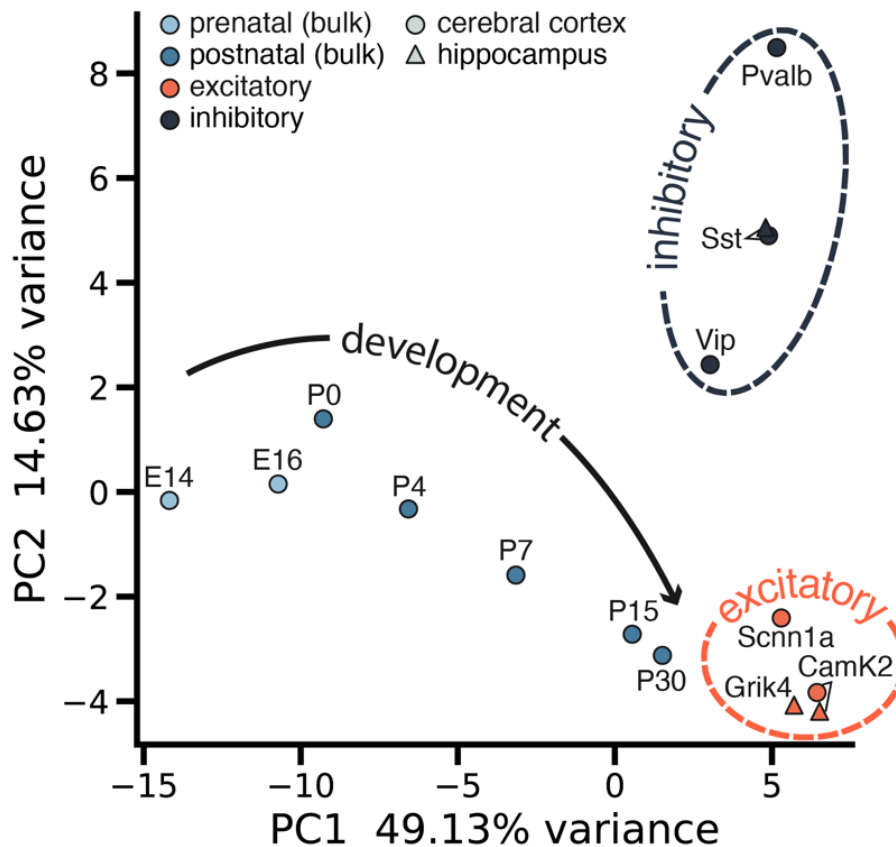

Figure 6 Principal component analysis of skipping exon events in the developing cortex and distinct neuronal cell types in the adult cortex and hippocampus. The developmental data are separated from left (E14) to right (P30) along the first principal component and show a bell-shaped curve with a peak at birth (P0). The different excitatory cell types (all mature cells) in the cortex and hippocampus are grouped into one small cluster (marked with an orange, dashed circle), while the inhibitory neurons form a looser cluster (marked with a blue, dashed ellipse). Data were analyzed and obtained from the web portal Cortexa³⁷.

1.1.3 Regulation of RNA binding proteins

Due to their ubiquitous relevance in developing and mature tissues, RBPs themselves are tightly regulated⁴² via several fail-safe mechanisms to ensure correct splicing activities⁴³. RBPs often have an autoregulatory feedback mechanism in which overexpression leads to changes in the splicing of their mRNAs and results in the production of fewer functional proteins. For example, the inclusion of a poison exon leads to the presence of premature stop codons and subsequently triggers nonsense-mediated decay (NMD)^{18,44}. Moreover, the induction of NMD is also a common mechanism through which RBPs can regulate other members of their family. A

prominent example is the PTBP family. Polypyrimidine tract binding protein 1 (PTBP1) binds to the pre-mRNA of *Ptbp2*, which results in the skipping of exon 10 with a frameshift mutation and a premature stop codon in exon 11. The premature stop codon marks the spliced mRNA for NMD; therefore, the expression of *Ptbp1* and *Ptbp2* is mutually exclusive⁴⁵.

Several non-autoregulatory mechanisms also play a crucial role in the posttranscriptional control of the expression levels of RBPs. For instance, microRNAs typically act as fine-tuners of gene expression^{46,47}. However, they have been reported to exert strong repressive effects on some RNA-binding proteins such as PTBP1 during cortical development. PTBP1 is a known repressor of neuronal differentiation due to its ability to induce non-neuronal splicing. It is widely expressed in non-neuronal tissues and absent in neurons⁴⁸. Makeyev and colleagues previously showed that miR-124-3p strongly repressed *Ptbp1* and the miRNA's expression in a neuroblastoma cell line was sufficient to induce neuronal differentiation. Normally, this process requires serum starvation or retinoic acid treatment⁴⁵. This example of strong microRNA repression highlights the relevance of the interplay between RBP-dependent alternative splicing and miRNA regulation during cortical development.

1.1.4 RBFOX

The RNA-binding Fox-1 homologs (RBFOX) represent a prominent family of RNA-binding proteins. RBFOX1 was the first discovered paralog and was originally named Ataxin 2-binding protein because of its interaction with *Ataxin 2*⁴⁹. The name Rbfox was derived from an orthologous gene in *C. elegans*, *fox-1*, that is involved in the sex-determination process of the species^{50,51}.

The number of paralogs within the RBFOX family varies between different species. For example, less complex animals, such as the invertebrate *Drosophila melanogaster*, rely on a single RBFOX protein. Mammals are known to have three RBFOX paralogs, namely, RBFOX1 (FOX1 or A2B1), RBFOX2 (FOX-2 or RBM9), and RBFOX3 (FOX-3, HRNBP3, or NeuN). All three RBFOX members share a highly conserved RNA recognition motif with very high sequence similarity⁵², they regulate largely overlapping target sets²², and have high sequence similarity (**Figure 7c**)^{36,52}.

The origin of multiple redundant RBFOX paralogs lies in sequence duplication and subsequent labor division and specification (**Figure 7b**)⁵⁰. Therefore, *Rbfox1-3* are expressed in a tissue-, cell type-, and time-specific manner (**Figure 7b, d**). RBFOX1 is expressed in the brain, heart, and skeletal muscle. RBFOX2 is more ubiquitously expressed throughout multiple organs and tissues, such as in the nervous system, heart, and ovary. RBFOX3, which is also often used as a specific neuronal nuclear marker, is predominantly expressed in neurons (**Figure 7b**)⁵³. *Rbfox2* is up-regulated in the transition from neuronal progenitor cells to neurons³⁸. During the development of the cerebral cortex, this is comparable with peak expression at E16 (**Figure 7d**). *Rbfox1* and *Rbfox3* are also expressed in the neocortex; however, their expression peaks at a much later developmental stage - P30 (**Figure 7d, middle**).

In mature neurons (P30 or older), *Rbfox1* and *Rbfox3* show distinct expression patterns between glutamatergic and GABAergic neurons (**Figure 7d, right**). Nevertheless, their depletion does not contribute to a shift toward a GABAergic splicing pattern, contrary to other differentially expressed RBPs, such as *Mbnl1/2* or *Khdrbs3*⁵⁴. This might be due to the compensatory effect that is at least apparent for RBFOX1 and RBFOX2^{29,32,38}. An array of known regulatory mechanisms controls the abundance and effectiveness of RBFOX proteins in the cell (**Figure 7e**). *Rbfox1* and *Rbfox2* possess a highly conserved binding motif close to their singular RRM, and binding of an RBFOX protein induces partial exclusion of the RRM. The resulting RBFOX Δ RRM has a significantly reduced binding affinity⁵⁵. RBFOX3 can include a poison exon in *Rbfox2*, leading to subsequent degradation via the NMD pathway⁵⁶, a mechanism that could play a crucial role in neurons due to the pan-neuronal presence of RBFOX3. Additionally, all *Rbfox* paralogs are subject to miRNA regulation. The translation of *Rbfox1/3* is inhibited by miR-129-5p⁵⁷, and *Rbfox2* is regulated by miR-92a-3p³⁸. However, potentially, more microRNAs target *Rbfox*. For example, TargetScan version 7.2 predicts 35 additional miRNAs to target the 3'-UTR of *Rbfox2* that are expressed in the embryonic neocortex^{38,47,58}. Specifically, for *Rbfox2*, excess levels can be sequestered by SNORD116, to which the protein binds without initiating any splicing changes⁵². These manifold regulatory mechanisms highlight the importance of the precise amount of RBFOX in cells. Therefore, it is unsurprising that mutations in RBFOX are implicated in several neuronal and cardiac disorders. RBFOX1 has been identified as an autism spectrum disorder risk gene⁵⁹ and is associated with idiopathic

generalized epilepsy⁶⁰. RBFOX2 is highly expressed in diabetic hearts. However, the RBFOX2 Δ RRM is the most abundant form, which subsequently leads to impaired splicing⁶¹. Mutations in *Rbfox2* were enriched in a large patient cohort with congenital heart disease⁶². In a knockout study of *Rbfox3*, reduced splicing of RBFOX3 was shown to be linked with epilepsy⁶³.

Due to their prominent function in mediating alternative splicing, all three RBFOX proteins preferably bind to the (U)GCAUG sequence located within the intronic regions of mRNA and exert a position-dependent splicing effect (**Figure 7a**). In general, binding upstream to a regulated exon promotes exon skipping, while downstream binding is associated with exon inclusion⁶⁴. The RBFOX motif is further found to be enriched in intronic regions flanking alternatively spliced exons for known RBFOX expression sites (**Figure 7b**), e.g. the heart, skeletal muscle, and cerebellum⁶⁵.

Figure 7 a Schematic representation of RBFOX protein functions: alternative splicing regulation, mature mRNA stability control, inhibition of miRNA biogenesis, and protein-protein interactions. **b** Heatmap showing expression levels of RBFOX1, RBFOX2, and RBFOX3 across various human tissues and cell types. Data from human protein atlas⁶⁶ **c** Phylogenetic analysis of RBFOX paralogs in *Mus musculus*. The canonical protein sequences were obtained from UniProt and aligned using the Clusta algorithm. Afterward, the phylogenetic tree was constructed using the neighbor-joining method within the MegaX software⁶⁷. **d** Expression pattern of *Rbfox1-3* in NPCs/neurons (E14)⁶⁸, throughout

development (E14-P30) in the neocortex⁸, and in mature neocortical/hippocampal neurons sorted according to marker genes²³. Data were obtained from the web portal Cortexa³⁷. **e** Regulatory mechanisms ensuring precise RBFOX levels: regulatory feedback loop of RBFOX1 and RBFOX2, RBFOX3 induced NMD of *Rbfox2*, splicing of the RRM to reduce the binding affinity of RBFOX, miRNA suppression, and sequestering.

Although solo RBFOX binding is sufficient to initiate alternative splicing, RBFOX can also be part of the large assembly of splicing regulators (LASRs), multiprotein complexes that are bound by protein-protein interactions. Here, RBFOX can indirectly alter splicing activity through interactions with hnRNPM or it can bind with the entire complex to its preferred (U)GCAUG motif⁶⁹.

In addition to its canonical function in alternative splicing, RBFOX is also involved in other transcriptional regulatory processes⁵⁰. RBFOX2 can recognize and bind to its motif located in the terminal loop of pri-miRNA and subsequently block processing by Drosha within the nucleus. The binding of RBFOX2 results in a significant reduction in the expression of miR-20b and miR-107 *in vivo* and *in vitro*, while the absence of RBFOX2 significantly increases the abundance of these two microRNAs. Furthermore, many other predicted target miRNAs of RBFOX have not been identified⁷⁰. In addition, RBFOX3 can enhance the processing of pri-miRNAs via the Drosha complex⁷¹. RBFOX can also be located outside the nucleus in the cytoplasm⁷², but to date, there have been no reports on whether RBFOX also binds pre-miRNA in the cytoplasm and thus potentially regulates pre-miRNA.

A known function of cytoplasmic RBFOX is the regulation of mRNA stability in the cytoplasm. It has been reported that RBFOX1 binds to the 3'-UTR, consequently blocking the binding of miRNA and enhancing mRNA stability⁷³. However, the opposite effect has also been described in *Drosophila melanogaster*, where binding in the 3'-UTR was associated with modestly decreased mRNA stability⁷⁴. Additionally, RBFOX2 acts as a transcriptional repressor⁷⁵; but upon *Rbfox2* overexpression, only a few changes in gene expression have been observed compared to those under control conditions³⁸.

1.2 MicroRNA regulation

MicroRNA regulation of gene expression is a ubiquitous phenomenon in higher eukaryotes⁷⁶. miRNAs are a class of small RNAs that have a length of ~22 nt⁷⁷, comprising a diverse class of regulators in *Mus musculus* and other mammals, showing distinct temporal and cell type-specific expression patterns in the developing and mature neocortex^{47,78}. miRNAs bind in the cytoplasm to the 3'-UTR of mRNAs and subsequently initiate rapid degradation⁷⁹. Therefore, miRNAs are generally fast posttranscriptional repressors of gene translation.

1.2.1 Biogenesis of microRNAs

Despite the existence of noncanonical miRNA pathways (see Shang et al., 2023 for review⁷⁶), most miRNAs are processed through the canonical pathway (**Figure 8**). Knockout of *DROSHA*, *DICER*, and *XPO5*, members of the canonical miRNA biogenesis pathway, resulted in 96.5 %, 96 %, and 29 %², respectively, of the miRNAs being reduced to ≤ 0.1 -fold levels⁸⁰, highlighting the prevalence of the canonical pathway. MicroRNAs are transcribed from a few intergenic but mostly intragenic regions (introns or rarely exons) in DNA⁸¹ and form the well-recognized hairpin structure. First, a complex of the RNase III Drosha and two DGCRPs crops the hairpin base of the pri-miRNA. The resulting pre-miRNA is exported through Exportin 5 into the cytoplasm⁸². Here, another essential RNase III of the miRNA pathway, Dicer, cleaves the pre-miRNA close to the terminal loop. Thereafter, the miRNA consists of two strands, one encoding the mature miRNA and the other being the passenger miRNA (miRNA*). The miRNA forms a complex with the Argonaute protein, and together, they bind to the target mRNA. The mRNA is recognized by the seed sequence of the miRNA (6–8 nt long sequence).

² 75.5 % of miRNA were decreased by ≤ 0.5 -fold upon *XPO5* knock-out

Figure 8 Canonical miRNA biogenesis pathway. The pri-miRNA is cleaved by a protein complex consisting of Drosha and two DGCRB proteins. The resulting pre-miRNA is exported through Exportin 5 into the cytoplasm. Dicer removes the loop, and subsequently, the mature miRNA can bind together with Agonaute 1-4 to the target mRNA's UTR. Figure modeled after Shang et al., 2023⁷⁶.

This gives three possible 6-mers (positions 1 - 6, 2 - 7 and 3 - 8), two 7-mers (positions 1 - 7 and 2 - 8), and one 8-mer (position 1 - 8) for binding to the target mRNA. Moreover, in animals, mismatches in the binding sequence are frequently observed, expanding the set of predicted targets even further. However, many of the predicted targets remain unaffected by the presence of a miRNA, while other unpredicted mRNAs are regulated by this miRNA⁸³. One common issue in target prediction is the short seed sequence (6 - 8 nt) that is recognized by the miRNA in the 3'-UTR of the mRNA. In large genomic sequences, seed matches can often be found by chance. Therefore, some target prediction databases consider only conserved sequences (e.g., the widely popular TargetScan⁵⁸) and can eliminate many false positives with this strategy⁸⁴. In addition to the canonical target sites, i.e. those that contain the matching sequence within their 3'-UTR, there are functional noncanonical target sites. Hence, the exact mechanisms of miRNA target identification remain only partly understood.

1.2.2 Regulatory effect of microRNAs

Although the regulatory effect is often described as weak, regulation by microRNAs is crucial during brain development and maintenance of mature tissue^{7,47,85}. This was proven in a series of experiments in which essential proteins of the microRNA biogenesis pathway were knocked out, which is often complicated by lethality. However, successful knockouts of *Drosha*^{80,86}, *Dgcr8*^{87,88}, *Dicer1*^{80,80,89-93},

Exportin5^{80,89}, and *Argonaute*⁹⁴ have been reported. The consequences depend on the time point of knockout and range from severe developmental impairment to lethality⁹². Excitatory neurons in the hippocampus lacking *Dicer* *in vivo* have drastically altered dendritic branching, dendritic spine length, apoptosis, and axonal pathfinding⁹¹. However, early knockout of *Dicer1* is lethal until approximately embryonic day 8⁹⁰.

miRNA regulation of gene expression mostly involves fine-tuning rather than strong repression⁸⁵, but some miRNAs exert a strong silencing effect on their targets²⁸. When targeting dosage-sensitive genes (e.g. RNA binding proteins or transcription factors), the downstream effects of miRNA-binding can be significant⁸³. For example, the expression of miR-124-3p can lead to complete silencing of its target *Ptbp1*²⁸ with subsequent strong alterations in splicing patterns (see section 1.1.3 – Regulation of RNA binding proteins).

MicroRNAs play pivotal roles in cortical development as indicated by significantly altered expression patterns at different developmental stages⁴⁷. In particular, some miRNAs orchestrate corticogenesis (**Figure 9** a, b) by targeting developmentally relevant genes⁷.

Figure 9 Regulatory effect of microRNAs during cortical development **a** Heatmap on the left shows the expression of known relevant miRNAs during the development of the neocortex⁷ and miR-92a³⁸ at time points E14, E17, and P0⁴⁷; the heatmap on the right shows the expression of validated developmentally important miRNA targets⁸. Expression was normalized to the maximum value for E14, E16/E17, and P0 of the respective miRNA/gene. **b** Developmental GO terms of the targets regulated by the respective miRNAs, according to Lennox et al., 2018⁷. **c** Principal component analysis of microRNA expression during neocortical development³⁸. The main variance is encoded on PC1 (92.18 %), and E14 is separated from the two later stages, E17 and P0. **d** Principal component analysis of cell-specific miRNA expression in the neocortex for the inhibitory neurons Sst, Vip, pan-inhibitory Gad2-positive neurons, and excitatory Camk2a neurons⁷⁸. **e** Schematic representation of the PTBP1/PTBP2 switch during neural differentiation. PTBP1 induces the inclusion of a poison exon into the pre-mRNA of *Ptp2*, and the resulting mRNA is subsequently degraded by NMD. By the expression of miR-124-3p, *Ptp1* is degraded, and thus, the poison exon in *Ptp2* is not included⁴⁵. Therefore, the expression of PTBP1 and PTBP2 is mutually exclusive⁶⁵.

1.2.3 Regulation of the microRNA biogenesis pathway

Precise regulation of miRNAs is important for maintaining adequate expression levels. This is achieved through multiple mechanisms in the miRNA-biogenesis pathway (**Figure 10**). The microprocessor complex, which contains at least Drosha and DGCR8, is engaged in a complex regulatory circuit. DGCR8 stabilizes Drosha through protein-protein interactions (**Figure 10a**). Moreover, Drosha can reduce the stability of *Dgcr8* mRNA by cleavage and thereby suppress the expression of DGCR8 (**Figure 10b**). A reduced level of DGCR8 decreases the stability of Drosha itself and, thus the protein level^{95,96}. This cross-regulatory loop is thought to prevent harmful effects within the cell.

Furthermore, the microprocessing complex is regulated by multiple protein modifications. Drosha's stability is enhanced, and its degradation is inhibited by acetylation⁹⁷ and binding of TAR DNA-binding protein 43 (TDP43)⁹⁸ (**Figure 10c**), a known neuronal activity response factor⁹⁹. Thus, this is a potential mechanism of miRNA-mediated neuronal plasticity. The other essential part of the microprocessing complex, DGCR8, is also subject to protein modifications. Deacetylation of DGCR8 by histone deacetylase 1 leads to increased affinity for pri-miRNAs (**Figure 10c**)¹⁰⁰. Herbert et al. showed that the stability of DGCR8 increases significantly when DGCR8 is phosphorylated by ERK/MAPKs, thereby responding to extracellular cues (**Figure 10c**)¹⁰¹. Interestingly, DGCR8 is also regulated in an activity-dependent manner. Phosphorated MEPC2 sequesters DGCR8 and blocks it from forming a microprocessing complex with Drosha (**Figure 10c**). Upon neuronal stimulation, however, MEPC2 is dephosphorylated, releasing DGCR8 to process pri-miRNA in cooperation with Drosha¹⁰².

Pre-miRNAs are exported from the nucleus to the cytoplasm by Exportin 5 (XPO5). XPO5 is also involved in *Dicer* expression; thus, the overexpression of pre-miRNA leads to decreased levels of DICER in the cytoplasm and subsequently to less mature miRNA due to a lack of pre-miRNA processing capacity (**Figure 10f**)⁸⁹.

The expression of *Dicer* is regulated through a homeostatic feedback loop involving the miRNA let-7 (**Figure 10d, e**). Pre-let-7 is processed to let-7, like other miRNAs, by Dicer. Intriguingly, the binding of let-7 leads to miRNA-dependent degradation of *Dicer* mRNA and a reduction in Dicer protein expression. Since let-7 is processed through

the canonical miRNA biogenesis pathway, which requires Dicer, let-7 levels also decrease. Therefore, *Dicer* is not posttranscriptionally repressed, and protein level increases¹⁰³.

Figure 10 Regulatory mechanisms of microRNA biogenesis and processing **a** Protein-Protein interaction: DGCR8 forms a complex with Drosha in the microprocessor. **b** Transcriptional repression: The DGCR8-DROSHA complex binds to and cleaves *Dgcr8* mRNA, regulating its expression. **c** Protein modifications: Posttranslational modifications of DGCR8, including acetylation, TDP43 binding, and deacetylation. Phosphorylation of DGCR8 leads to sequestration by MECP2, affecting neuronal activity. **d** Dicer/let-7 feedback loop: lack of Dicer leads to reduced miRNAs and increased let-7 expression. Let-7 targets Dicer mRNA, creating a regulatory feedback loop. **e** Dicer/let-7 feedback loop interference: Lin-28 blocks the processing of pre-let-7, interfering with the feedback mechanism. **f** Dicer mRNA processing: Exp5 inhibits Dicer mRNA processing, resulting in accumulation of excess pre-miRNAs in the nucleus and reduced mature miRNA production.

1.3 Other posttranscriptional regulatory mechanisms

In addition to regulation through alternative splicing and microRNAs, other important mechanisms modulate gene expression. Although these are not within the scope of the thesis, they are briefly introduced here.

1.3.1 RNA modifications

RNA modifications are chemical changes to RNA molecules that can affect their stability, function, and interactions. Over 170 types of RNA modifications have been identified since the discovery of pseudouridine in the 1950s¹⁰⁴, with the abundant N6-methyladenosine (m6A) being one of the most studied¹⁰⁵. They were often neglected in the past due to low abundance and technical limitations in detection. Recently, RNA modifications have gained increasing interest, also in the context of cortical development¹⁰⁴. Advancements in high-throughput sequencing and mass spectrometry have allowed a more comprehensive and accurate profiling of RNA modifications. Direct RNA sequencing, particularly nanopore sequencing, has recently emerged as a promising method for detecting RNA modifications. Nanopore sequencing relies on changes in the electric current measured in the nanopore that are attributable to chemical alterations in RNA molecules. While these alterations make basecalling challenging, they also provide an opportunity for direct and comprehensive RNA modification detection^{106–108}. Consequently, it is now becoming possible to directly identify modifications such as m6A^{109,110} or pseudouridine^{111,112} simultaneously with standard RNA-seq experiments.

These recent technical advancements in detection methods have led to a greater appreciation of the critical roles RNA modifications play in regulating complex biological processes. For example, studies have revealed that m6A is dynamically regulated in the brain, influencing mRNA stability and neuronal plasticity¹¹³.

1.3.2 RNA localization

Cellular organization depends on the ability of the cell to localize its constituents, i.e., DNA, RNA, and proteins, to precise regions to carry out their functions. Specifically, mRNA was initially expected to be rarely transported to distal sites of the cell; however, it has become clear that mRNA is subject to localization regulation¹¹⁴. This represents

a significant expansion of the central dogma of biology, which postulates that mRNA simply transfers information from DNA to protein. The transport of mRNA to different subcellular compartments regulates the local proteome.

Transporting mRNA to the location where it is needed can offer several advantages, such as energy efficiency due to reduced cost of protein transport, and quick response to internal or external stimuli through repeated translation of the same transcript. This is particularly relevant in neurons, where neurites (axons and dendrites) can extend several hundred micrometers away from the cell body (in extreme cases up to several 100 centimeters) and thus require local protein translation. In rat hippocampal neurons, approximately 50 % of transcripts were found to be enriched in dendrites compared to the soma¹¹⁵, demonstrating the capability of neurons for local protein homeostasis. Subsequently, all relevant components for synthesis of cytosolic proteins (tRNA, mRNA, miRNA, translation factors, RISC, and ribosomes) have been detected within synaptic areas^{116,117}.

In general, there are three mechanisms for RNA localization described:

1. **Local protection of mRNA from degradation:** In synapses, RNA-binding proteins can shield transcripts from degrading enzymes, allowing for longer persistence and local translation. This mechanism is crucial in synapses because local protein synthesis allows for rapid, spatially specific responses to synaptic stimulation, i.e., synaptic tuning¹¹⁸.
2. **Diffusion and anchoring:** mRNA can diffuse throughout the cell and be anchored at specific locations, such as synapses, through interactions with local cytoskeletal elements or specialized anchoring proteins¹¹⁹.
3. **Active transport:** mRNA can be actively transported to specific subcellular locations through direct or indirect interactions with cytoskeletal elements and motor proteins such as kinesins and dyneins¹¹⁹. RNA granules, containing mRNAs bound to specialized RBPs like Staufen, play a key role in this transport and localization process^{120,121}.

Central to the active transport mechanism are cis-acting elements, often found in the 3'-UTR of the mRNA. These RNA sequences act as "zip codes" that direct mRNA to particular subcellular locations and are recognized by RBPs, facilitating the mRNA's transport and localization¹²². To prevent premature translation, mRNAs

are often transported and maintained in a translationally repressed state and activated by synaptic stimuli¹¹⁸.

1.3.3 Polyadenylation

Polyadenylation is an essential process in the biogenesis of mRNA. This posttranscriptional modification involves the addition of a poly(A) tail to the 3' end of mRNA, significantly influencing its stability, localization, and translation efficiency¹²³. A primary function of the poly(A) tail is to protect mRNA from degradation, with longer tails generally associated with increased mRNA stability.

The poly(A) tail is generated directly after transcription by the non-templated addition of adenosines to the mRNA 3'-end, a process catalyzed by nuclear poly(A)-polymerases. The initial length of poly(A) tails generated by this process has been estimated to be around 250 nucleotides *in vitro*, consistent with the typical length observed in mammals. After nuclear export, poly(A) length is dynamically regulated by the interplay of 3'-to-5' degradation through exoribonucleases, poly(A) tail stabilization via poly(A) tail binding proteins, and elongation by cytoplasmic poly(A)-polymerases⁹.

As poly(A) tails are shortened throughout the lifetime of the mRNA, deadenylation is one of the main factors determining the mRNA half-life¹²⁴. While it has been shown that the poly(A) tail has a regulatory role, it is still not fully understood whether a specific length allows for specific regulatory outcomes. A minimal poly(A) tail is needed to prevent quick degradation, yet hyperadenylated RNAs are marked for fast RNA degradation in the nucleus¹²⁵.

Beyond tail length regulation, alternative polyadenylation (APA) adds another layer of complexity to gene expression control. While polyadenylation typically occurs at the 3'-UTR, alternative polyadenylation sites can exist within introns or coding regions. This phenomenon produces different mRNA isoforms from a single gene, each potentially having distinct characteristics. These isoforms may possess altered 3'-UTRs, which can significantly impact the mRNA's stability, localization, and translation efficiency. In some instances, APA can even result in the generation of altered protein products, further expanding the diversity of gene expression outcomes¹²⁶.

1.4 Scope and outline of the thesis

The following thesis comprises five studies that demonstrate how integrative bioinformatics and deep learning techniques can be leveraged to study the role of posttranscriptional regulation during cortical development. A summary of the main findings of each study is provided below.

- **Study 1: Premature upregulation of miR-92a's target RBFOX2 hijacks PTBP splicing and impairs cortical neuronal differentiation.** This study focused on elucidating the role of RBFOX2 in mediating alternative splicing changes that occur during corticogenesis. Premature overexpression of *Rbfox2* in mouse embryos at E14 was associated with impaired neuronal differentiation and migration and a mixed neuron- and NPC-like splicing pattern. Furthermore, we identified a set of significantly included cassette exons that are otherwise repressed by PTBP2 at this developmental time point. The antagonistic splicing relationship between these two RNA-binding proteins highlights the importance of precise temporal expression of alternative splicing factors in the developing brain. Consequently, we identified miRNA 92a-3p-mediated silencing as an important posttranscriptional mechanism to ensure appropriately low expression levels of *Rbfox2* in NPCs.
- **Study 2: Stage-specific expression patterns and co-targeting relationships among miRNAs in the developing mouse cerebral cortex.** miRNAs play an important role in the development of the neocortex. They act as posttranscriptional repressors by binding to the 3'-UTR of their target mRNA, thereby inhibiting translation or initiating degradation. Through miRNA-seq at three key time points during corticogenesis (E14, E17, and P0) and in NPCs and *in vitro* differentiated neurons, we identified microRNAs that regulate genes involved in crucial developmental processes such as stem cell maintenance, cell fate commitment, neuronal differentiation, and alternative splicing. A weighted co-expression network analysis revealed several microRNAs acting as hubs at early and late embryonic brain developmental stages. Moreover, using a custom statistical pipeline, we constructed an interaction network of miRNAs sharing more targets than expected by chance. Using luciferase

assays, we showed that the cooperative binding of two miRNAs to the same target could increase the repressive effect compared to individual miRNAs.

- **Study 3: Cortexa: a comprehensive resource for studying gene expression and alternative splicing in the murine brain.** Cortexa is a web portal designed to facilitate the analysis of RNA-sequencing datasets focusing on gene expression and alternative splicing in the mouse cerebral cortex and hippocampus. Gene expression and alternative splicing significantly change during cortical development, and both processes differ between distinct cell types in the adult brain. We reanalyzed three transcriptomic datasets (longitudinal development, neuronal cell-type specific, and NPC/neuronal datasets) concerning gene expression and alternative splicing and integrated them into the cortexa web portal (www.cortexa-rna.com). Furthermore, we implemented SplicePCA as an integrative method for studying global alternative splicing patterns. Cortexa provides a valuable resource accessible to a broad range of scientists, as it includes understandable visualizations as well as global and single-gene level representations of gene expression and alternative splicing. Users, furthermore, have the option to integrate their data and compare them with the data sets already available in cortexa.
- **Study 4: More than a pore: How voltage-gated calcium channels act on different levels of neuronal communication regulation.** Voltage-gated calcium channels (VGCC) are key regulators of calcium influx into the cell. They are activated upon depolarization of the membrane, and the subsequent increase in cellular calcium leads to the fusion of vesicles and neurotransmitter release into the synaptic cleft. Since VGCCs are multi-subunit structures composed of alpha, beta, gamma, and alpha-2-delta subunits, they exhibit many functions beyond the conductance of Ca^{2+} . Thus, alternative splicing of VGCCs is a primary mode of modifying their molecular interactions and downstream signaling capabilities. Here, we analyzed ribosome-associated transcripts and specifically focused on alternative splicing between various cell types in the neocortex and hippocampus. This revealed distinct VGCC splicing patterns across the neuronal populations, with parvalbumin-positive interneurons exhibiting a particularly unique splicing pattern.

- **Study 5: Denoising functional imaging data for neurobiology.**
Posttranscriptional regulation often results in subtle changes in neuronal function, which can be read at synaptic connections between neurons. Noise in imaging data can further obscure these minute alterations, particularly in techniques like glutamate imaging that aim to capture fast events of transmitter release. This study introduces Neuroimage Denoiser, a U-Net-based deep learning model specifically designed to reduce noise in microscopic recordings of fast synaptic events. The framework effectively preserves signal amplitudes while significantly improving the signal-to-noise ratios, enabling more accurate detection and analysis of synaptic responses. Neuroimage Denoiser can be applied to recordings with different acquisition rates and sensors without retraining, making it a versatile tool for various experimental setups. This approach enhances the ability to study complex synaptic structures, spontaneous activity, and synaptic plasticity at high temporal and spatial resolutions. Thus, it is a flexible tool for studying synaptic alterations induced by posttranscriptional regulation, such as the alternative splicing of calcium channels. The tool is open-source and available on GitHub (https://github.com/s-weissbach/neuroimage_denoiser).

19 Abstract

20 RBFOX2 is an RNA-binding protein crucial for alternative splicing regulation and
21 implicated in several neurodevelopmental disorders. Here, we show that while
22 RBFOX2 is present only at low levels in neural progenitor cells (NPCs), it is
23 upregulated in differentiating neurons of the mouse embryonic neocortex. *In-utero*-
24 electroporation-induced overexpression resulted in a cellular phenotype characterized
25 by impaired neuronal migration and differentiation. Genome-wide analysis at E15.5
26 revealed numerous alternative splicing events associated with a mixed NPC- and
27 neuron-like splicing pattern and a significant deviation from the normal splicing
28 developmental trajectory. Remarkably, premature *Rbfox2* overexpression induced the
29 inclusion of validated target exons that are otherwise repressed by PTBP2, indicating
30 an antagonistic splicing relationship between these two RNA-binding proteins and
31 highlighting the necessity for strict temporal regulation of their expression during
32 embryonic brain development. Consequently, we showed that the NPC-specific
33 miRNA 92a-3p reduced the expression levels of *Rbfox2* *in vitro*. Furthermore, silencing
34 miR-92a-3p *in vivo* in the embryonic neocortex led to a significant increase in *Rbfox2*
35 levels. Our results therefore demonstrate that RBFOX2 is a crucial player in the NPC-
36 to-neuron splicing switch. Furthermore, we present a novel post-transcriptional
37 mechanism for controlling RBFOX2 levels during early neuronal differentiation via miR-
38 92a-3p silencing.

39

40 Introduction

41 Despite the presence of only approximately 22,000 protein-coding genes¹, the murine
42 neocortex, and hippocampus exhibit a considerable diversity of neurons, amounting to
43 388 transcriptomic cell types, as reported by the Allen Brain Consortium². A key factor
44 enabling this diversity and complexity is alternative splicing (AS), a tightly regulated
45 process that governs the production of multiple mRNA isoforms from a single gene.
46 Intriguingly, nearly every multi-exon gene in the human genome can undergo
47 alternative splicing, generating numerous protein isoforms with distinct structural and

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

48 functional properties³. This vast molecular diversity expands the proteome's complexity
49 without necessitating a proportional increase in the genome's size. Within the nervous
50 system, AS is a pervasive phenomenon, with various neural genes subject to this
51 regulation⁴. Overall, AS has a higher prevalence across different species and is more
52 conserved in the brain compared to other tissues^{5,6}.
53 Specifically, numerous changes in the splicing landscape occur in the developing brain
54 with high temporal precision^{4,7}. Among the processes that require correct splicing are
55 neuronal migration, neuronal differentiation⁸, axonogenesis⁹, and synaptogenesis^{10,11}.
56 Notably, the significance of correct splicing is not confined to the developing brain
57 alone. In the adult brain, different neuronal types exhibit distinct splicing patterns,
58 further underscoring the importance of alternative splicing in maintaining the brain's
59 functional diversity^{11,12}.
60 During embryonic development, neural stem cell differentiation requires precise
61 extensive AS switches to create neuron-specific splicing patterns. Many of these
62 splicing events alter key protein domains, particularly in proteins of the cytoskeleton⁸.
63 Various RNA binding proteins (RBPs) regulate the transition from neural stem and
64 progenitor cells to neurons by altering the splicing pattern of target genes, therefore
65 their temporal expression needs to be strictly regulated. Here, microRNAs (miRNAs)
66 that suppress gene expression post-transcriptionally by binding to the 3' untranslated
67 region of target mRNAs¹³⁻¹⁶, represent one important mechanism for mediating stage
68 and cell-type specific levels of RBPs. For instance, PTBP1 is expressed only in neural
69 stem and progenitor cells, however, it is strongly repressed by miR-124-3p in
70 neurons¹⁷. In contrast, other prominent RBPs, including NOVA, PTBP2, MBNL2, and
71 RBFOX are predominant in neurons. These RBPs act in both synergistic (e.g. NOVA
72 and RBFOX) and antagonistic relationships (e.g. PTBP1/2 and RBFOX)^{18,4,8}.
73 The RBFOX-family consists of three paralogs, namely, RBFOX1 (FOX-1 or A2B1),
74 RBFOX2 (FOX-2 or RBM9) and RBFOX3 (FOX-3, HRNBP3, or NeuN). The
75 association of mutations in human *RBFOX1* and *RBFOX2* with intellectual disability,
76 autism, and other neurodevelopmental disorders, as well as the specific neurological
77 phenotypes observed in *Rbfox* knockout mice, highlight the important functions of
78 these proteins during neurodevelopment¹⁹⁻²⁶. All RBFOX-proteins have a single, highly
79 conserved RNA recognition motif (RRM) that binds to the target sequence (U)GCAUG
80 harbored in the premature mRNA and initiates position-dependent splicing. RBFOX
81 binding in the intronic region upstream of an alternatively spliced exon promotes its
82 exclusion from the mature mRNA whereas downstream binding leads to inclusion²⁷.
83 Moreover, in humans, all RBFOX-proteins share the position-dependent splicing
84 mechanism and the RRM which is identical in RBFOX1 and RBFOX2 and almost
85 identical in RBFOX3. Therefore, the RBFOX family can act in a functionally redundant
86 manner²⁸. However, the temporal expression patterns of these proteins diverge
87 significantly, exhibiting variations across different tissues and cell types^{2,12}. In the
88 developing brain, RBFOX proteins are either lowly expressed or not present in neural
89 stem cells, but they are highly expressed in neurons which is in agreement with their
90 role in promoting neuronal differentiation. Studies aiming at identifying splicing
91 changes during neural stem cell differentiation have compared alternative exon usage
92 between NPCs and neurons by RNA-sequencing^{8,29}. While these studies have
93 identified numerous splicing changes that are presumably driven by RBFOX binding,
94 the exact role of RBFOX during neuronal differentiation in the embryonic brain has not
95 been elucidated yet.

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

96 In the current study, we identified extensive AS changes upon premature *Rbfox2*
97 overexpression (*Rbfox2*-OE) in the embryonic neocortex, specifically related to genes
98 that are important for neuronal differentiation and localization. Remarkably, we
99 observed a mixed neuronal and NPC-like splicing pattern that significantly deviated
100 from the normal cortical splicing trajectory. In line with this, *Rbfox2* overexpression
101 increased the percentage of neural stem and progenitor cells and blocked
102 differentiation into neurons on the cellular level. Since a precise and tight control of
103 RBFOX2 is essential for proper neuronal differentiation in the embryonic neocortex,
104 we investigated if miRNAs might repress *Rbfox2* expression in NPCs. Indeed, we
105 observed that the NPC-specific miR-92a led to reduced RBFOX2 levels. Conversely,
106 miR-92a silencing in the embryonic neocortex was associated with a concomitant
107 increase in *Rbfox2* expression.

108

109 **Results**

110 RBFOX2 is predominantly expressed in neurons

111 The RBFOX protein family exhibits distinct temporal expression patterns, varying also
112 by cell type. For instance, RBFOX1 and RBFOX3 are expressed in mature neurons
113 and exclusively in the cortical plate in the embryonic cerebral cortex³⁰ RBFOX2 shows
114 early expression in Purkinje cells in the cerebellum³¹. To elucidate the composition of
115 RBFOX proteins in the mouse embryonic cerebral cortex, we co-stained sections for
116 RBFOX1 and RBFOX2. This confirmed RBFOX2's presence was not limited to the
117 neuron-specific cortical plate, but it was also expressed in the intermediate and
118 ventricular (VZ)/subventricular (SVZ) zones (Figure 1a). In contrast, RBFOX1
119 expression was restricted to the cortical plate/subplate. While this broader expression
120 pattern of RBFOX2 compared to RBFOX1 was evident, not all cells in the cerebral
121 cortex showed positive RBFOX2 staining. Especially in the VZ/SVZ where radial glia
122 cells and basal progenitors reside at this developmental stage, the majority of cells
123 were RBFOX2 negative (Figure 1a). This prompted us to investigate the temporal
124 expression of RBFOX2 using an *in vitro* neuronal differentiation model. Here, we
125 observed low *Rbfox2* mRNA expression in radial glia-like cells and early neural
126 progenitor cells (NPCs). However, *Rbfox2* expression increased significantly during
127 neuronal differentiation, peaking in late NPCs and young neurons (Figure 1b).
128 Likewise, *Rbfox2* was only weakly expressed in NPCs derived from the embryonic
129 cerebral cortex while it was strongly upregulated in cortical neurons at both RNA and
130 protein levels (Figure 1c, d).

131 To further corroborate these data, we analyzed RBFOX2 expression in the embryonic
132 cerebral cortex *in vivo* by immunostaining. To this end, we made use of a transgenic
133 mouse model (HES5::GFP) expressing GFP exclusively in Notch-signaling neural
134 progenitor cells. In agreement with the *in vitro* data, RBFOX2 expression was restricted
135 to GFP⁻ cells, that were presumably in a more differentiated state compared to HES5
136 positive NPCs (Figure 1e). Co-stainings with the basal progenitor marker TBR2
137 (EOMES) confirmed the absence of RBFOX2 from neural progenitor cells. Only cells
138 with a low TBR2 expression exhibited low RBFOX2 expression, suggesting that these
139 cells were currently differentiating into neurons (Figure 1f). In contrast, RBFOX2 was
140 highly expressed in newborn neurons in all zones as revealed by co-staining with the
141 early neuron marker β -III-Tubulin (TUBB3) (Figure 1g). In summary, RBFOX2 was
142 weakly expressed in neural stem and progenitor cells and highly upregulated during
143 neuronal differentiation, highlighting its potential role in mediating the neuron-specific
144 splicing switch.

180 To study RBFOX2's impact on splicing during embryonic corticogenesis, we used *in-*
181 *utero* electroporation to overexpress *Rbfox2* in the mouse cerebral cortex at E13.5 and
182 subsequently performed RNA-sequencing at E15.5 (Figure 2a). As expected, *in utero*
183 electroporation resulted in a significant increase in *Rbfox2* gene expression ($p_{adj} <$
184 0.0001 , $\log_2\text{fold} = 5.754$, Figure 2b). Furthermore, we detected 268 differentially
185 expressed genes (Supplementary Figure S1a, Supplementary Data 1) and substantial
186 changes in the alternative splicing landscape upon *Rbfox2* overexpression compared
187 to control samples (Figure 2c). However, most alternatively spliced genes did not show
188 altered expression levels. Only 30 genes were alternatively spliced and differentially
189 expressed at the same time (Figure 2d) with *Snhg5*, a lncRNA, having all five types of
190 analyzed splicing events. 17 genes were alternatively spliced and upregulated, while
191 the remaining 13 were downregulated. While frameshifts induced by alternative
192 splicing can result in early stop codons and nonsense-mediated decay (Figure 2f), we
193 did not find significant changes in gene expression related to this phenomenon in our
194 data.

195 Overall, we detected 2,208 significant alternative splicing events (Figure 2e,
196 Supplementary Figure S2) between the *Rbfox2*-OE and control samples using a
197 stringent threshold of $FDR < 0.01$ and $|\Delta PSI| > 0.1$. Skipped exons (or cassette exons)
198 represented $\sim 71\%$ of these events. Changes in splicing could mostly be attributed
199 directly to RBFOX2 and not to altered expression of other known splice factors relevant
200 during cortical development (Figure 2g). In line with this, we observed a significant
201 overlap between skipping exon events in our data with *Rbfox* triple knock-out (*tRbfox*-
202 KO) samples³² (fold enrichment ≈ 9.833 , p -value < 0.0001 ; Supplementary Figure 3b,
203 Supplementary Data 2). Importantly, inclusion levels of cassette exons present in both
204 data sets were strongly negatively correlated ($R = -0.6624$, $p < 0.0001$) indicating that
205 *Rbfox2*-OE induced the opposite splicing regulation compared to *tRbfox*-KO.
206 (Supplementary Figure 3a). The strong *Rbfox2*-OE induced a significant reduction in
207 the expression level of *Rbfox1* ($p_{adj} < 0.0001$, $\log_2\text{fold} = -1.342$). However, the
208 expression of *Rbfox3* was unaltered ($p_{adj} \approx 0.98$, $\log_2\text{fold} = 0.121$) compared to the
209 control group. Remarkably, genes that were alternatively spliced in our analysis were
210 significantly enriched for high-confidence neurodevelopmental disorder (NDD) genes³³
211 (224 out of 1317 genes, fold enrichment ≈ 1.358 , $p < 2e-07$, Supplementary Data 6,
212 Supplementary Figure S4).

213 Alternative splicing is a key mediator for the development of proper neuronal
214 functioning. Over 20,000 splicing events have been reported throughout cortical
215 development³⁴. To gain a perspective on the splicing pattern induced upon *Rbfox2*-
216 OE, we integrated the previously published RNA-sequencing data from Weyn-
217 Vanhentenryck et al. obtained at different developmental stages of wildtype mouse
218 cerebral cortex (E14.5 to P30)³⁴ as well as RNA-sequencing from FACS-sorted NPCs
219 and neurons²⁹. The hierarchical clustering of splicing events that were significant both
220 in our data and in the previous studies, revealed that our control group clustered with
221 the FACS-sorted neurons as well as with the E14.5 and E16.5 cortical samples. In
222 contrast, the *Rbfox2*-OE group did not closely cluster with any of the embryonic

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

223 samples or NPCs/neurons pointing to an abnormal splicing pattern (Supplementary
224 Figure S2).

225 To further investigate the impact of *Rbfox2*-OE on the splicing landscape during
226 neurogenesis, we applied a principal component analysis (PCA). We observed a bell-
227 shaped trajectory indicative of the expected splicing changes throughout embryonic
228 and postnatal cortical development (Figure 3a). Remarkably, the influence of batch
229 effects between the different studies was negligible, contrary to differential gene
230 expression analyses where batch effects are often prominent^{35,36}. *Rbfox2*-OE resulted
231 in a substantial deviation from this expected developmental trajectory. Specifically, on
232 the first principal component (PC1), *Rbfox2*-OE exhibited a shift towards the splicing
233 pattern associated with mature neurons, while on the second principal component
234 (PC2), the shift was towards undifferentiated NPCs. To identify the main splicing
235 events that explained the observed splicing pattern, we calculated the loadings of the
236 original variables included in the PCA on both PC1 and PC2 (Figure 3b). This analysis
237 revealed numerous genes that are highly relevant for neuronal development.
238 Interestingly, some genes with the highest loadings were associated with
239 neurodevelopmental diseases. For instance, *Shank1* and *Dlgap4* are related to autism
240 spectrum disorder^{37,38}, whereas *Dlg2* has been linked with schizophrenia³⁹.

241 To gain insight into the biological processes regulated by the genes that were
242 correlated with each principal component, we performed a gene set enrichment
243 analysis (GSEA) of gene ontology (GO) terms. The loadings of the alternative splicing
244 events on each principal component were used as effect sizes in the GSEA (Figure
245 3c). PC1 was associated with higher-level GO terms such as “regulation of
246 transportation”, “animal organ development”, and “central nervous system
247 development”. This association is plausible given that PC1 represented 55.61% of the
248 variability and separated the samples from early embryonic stage E14.5 to the
249 prepubescent stage P30. During this broad period, manifold biological processes
250 occur, shaping the development of the central nervous system. The higher-level GO
251 terms reflected this complexity as descriptors for the wide-ranging changes captured
252 by PC1. More specifically, transport and localization were significantly enriched for
253 PC1. Interestingly, some splicing events with high PC1 loadings were associated with
254 multiple enriched GO terms. For instance, *Cadps*, a calcium-dependent segregation
255 activator, that was associated with 7 GO terms (Supplementary Data 3), was previously
256 reported to be differentially spliced upon *Rbfox2*-knockout²³. This gene was also
257 among the top correlated genes of PC1 (Figure 3b, left). Another important gene
258 associated with 6 GO terms was *Ap2a1*. While PTBP2 was previously reported to
259 induce exon skipping in *Ap2a1* (chr7:44,552,885-44,552,951, Supplementary Figure
260 S5a) during brain development⁴⁰, *Rbfox2*-OE led to the opposite effect of exon
261 inclusion (FDR < 0.0001, Δ PSI = 0.297) in our data.

262 Moreover, neuron differentiation was among the significant terms associated with PC2,
263 where the *Rbfox2*-OE samples were more similar to an NPC splicing pattern. When
264 analyzing the splicing events that significantly contributed to this GO term, we identified
265 several developmentally relevant genes. For instance, *Clasp2*, a protein involved in
266 microtubule dynamics, is known to play a role in neuronal migration and axonal growth
267 during cortical development⁴¹. We detected an alternatively spliced exon in *Clasp2*
268 (chr9:113,691,503-113,691,530, Supplementary Figure S5b) that showed a
269 significantly higher inclusion in the *Rbfox2* overexpression group (FDR < 0.0001, Δ PSI
270 = 0.118). Interestingly, we observed a similar increase of the same exon when

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

271 analyzing the splicing changes between NPCs and neurons (FDR < 0.01, Δ PSI =
272 0.118).

277 *to E14.5 to P30 samples from Weyn-Vanhentenryck et al.³⁴, squares represent NPC and neuron samples from Liu*
278 *et al.⁴³. Rbfox2 overexpression (OE) samples (triangle shape) noticeably deviate from the expected developmental*
279 *trajectory. b) Loading analysis for PC1 and PC2, highlighting the top 10 positively and top 10 negatively correlated*
280 *splicing events for each PC. Color gradient represents the Δ PSI values for Rbfox2-OE compared to control samples*
281 *c) Gene Set Enrichment Analysis (GSEA) performed on splicing events for PC1 and PC2 using loadings on each*
282 *component as effect sizes. d) Chord plot showing the association between significant splicing events in Rbfox2-OE*
283 *vs. control samples compared with splicing events in neurons vs. NPCs obtained using the data from Liu et al.⁴³.*

284 The observed mixed phenotype upon *Rbfox2*-OE was not only characterized by the
285 deviation from the expected developmental trajectory but also by the type of splicing
286 events. When comparing the significant splicing events upon *Rbfox2*-OE with those of
287 neurons vs. NPCs from the Liu et al. data⁴³, we found an overlap of 283 significant
288 events. Strikingly, 70% of the events corresponded to a neuron-like splicing and 30%
289 of events represent NPC-like splicing patterns (Figure 3d). Several of the overlapping
290 genes have been reported previously to undergo alternative splicing during important
291 developmental processes associated with NPC proliferation, radial migration of
292 neurons, and neuronal differentiation⁸. Genes with a neuron-like splicing included

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

293 *Clasp2*, *Dctn1*, *Kif2a*, *Mast2*, and *Tpm1*. In contrast, *Add1*, *Clip1*, *Clasp1*, *Dync1i2*,
294 *Gphn*, and *Macf1* were spliced in an NPC-like way (Supplementary Data 4).

295

296 RBFOX2 misexpression impairs neuronal differentiation in the embryonic 297 neocortex

298 After ascertaining the dramatic effect of *Rbfox2* overexpression on the splicing
299 landscape of the developing neocortex, next, we investigated whether this translates
300 into changes in neuronal differentiation and/or migration at the cellular level. Therefore,
301 we electroporated *Rbfox2* constructs into the E13.5 neocortex and analyzed brain
302 sections two days later by immunostaining experiments. We detected significantly
303 more RBFOX2-OE cells in VZ and IIZ. Conversely, we observed significantly fewer
304 RBFOX2-overexpressing cells in the ulZ and the CP (Figure 4a). In line with the
305 observed phenotype of cells detaching from the ventricular surface and subsequently
306 failing to migrate to the cortical plate and accumulating in the IIZ, *Rbfox2-OE* induced
307 alternative splicing of two key constituents of the Reelin pathway which plays an
308 important role during cortical development by guiding neurons to the correct position
309 in the CP⁴⁴. Specifically, an exon of *Lrp8* encoding the murine-specific eighth LDL
310 receptor type A (chr4:107,705,477-107,705,600, Supplementary Figure S5f) was
311 abnormally included (FDR < 0.0001, Δ PSI = 0.275). Expression of this exon was
312 previously linked to neuronal migration⁴⁵. Additionally, the exon (chr19:27,217,244-
313 27,217,370, Supplementary Figure S5g) of *Vldlr* encoding the calcium-binding EGF
314 domain was repressed following *Rbfox2-OE* (FDR < 0.0001, Δ PSI = -0.201).
315 Repression of the EGF domain alters the binding affinity to ligands modulating the
316 sensitivity of the receptor and its interacting ligands⁴⁶. Moreover, RBFOX2 could
317 synergistically act with NOVA2 which is known to induce alternative splicing changes
318 in *Dab1*. DAB1 constitutes a switch within the Reelin pathway that is required for
319 neuronal migration^{47,48}.

320 To investigate the impact of *Rbfox2* misexpression on neuronal differentiation, we
321 performed immunostainings with antibodies against the marker genes PAX6 (radial
322 glia cells), TBR2 (basal progenitors), and SATB2 (neurons). This revealed a significant
323 differentiation defect in the *Rbfox2* overexpressing neocortex. In particular, the
324 percentage of PAX6⁺ radial glial cells and TBR2⁺ basal progenitors was significantly
325 increased compared to the control group (Figure 4b,c) whereas the percentage of
326 SATB2⁺ neurons was reduced (Figure 4d). This indicates that a correct and fine-tuned
327 expression of RBFOX2 is essential for proper neuronal differentiation in the embryonic
328 neocortex.

336

337 RBFOX2 canonical and non-canonical motifs are enriched around alternatively 338 spliced exons

339 Previous studies have shown that RBFOX1, RBFOX2, and RBFOX3 preferably bind
340 to the conserved sequence (U)GCAUG^{49,50}. RBFOX's effect is position-dependent –
341 an upstream intronic binding leads to exon repression, while downstream intronic
342 binding enhances exon inclusion (Figure 5b)⁵¹. Therefore, we expected to find the
343 canonical motif to be enriched at either location according to the type of alternative
344 splicing events. We screened for all possible pentameric motifs in the 150 nt intronic
345 region directly flanking alternatively spliced cassette exons, accounting for their
346 occurrence in three distinct categories: significantly spliced-in (inclusion), significantly
347 skipped (repression), and unregulated exons (background). To mitigate bias from
348 motifs with higher genome-wide occurrence, we adjusted motif counts of significant
349 splicing events by subtracting background counts and subsequently converted these
350 to z-scores (see Methods).

351 As expected, the canonical RBFOX motif was enriched downstream of included exons
352 and upstream of repressed exons (Figure 5a). The motif GCAUG was associated with
353 the strongest enrichment, both for upstream binding & exon repression (z-score: 6.8)
354 and downstream binding & exon inclusion (z-score: 9.4). Moreover, shifted motifs such
355 as UGCAU and CAUGC were also enriched and had a high correlation with GCAUG
356 ($r > 0.8$; Supplementary Figure S6). Subsequently, we analyzed the position of the
357 canonical GCAUG for exon inclusion and repression events (Figure 5c). We
358 discovered motifs that promote exon skipping, located both within ~ 100 nt upstream of
359 the alternatively spliced exon and on the exon itself. Exon inclusion was related to
360 GCAUG occurrence within ~ 150 nt downstream of the exon. These findings are in line
361 with previous reports on the position-dependent splicing activity of RBFOX2^{52,53}.

362 However, we found additional motifs known to be bound by other splicing factors. For
363 instance, UGCUU (z-score 4.9, downstream & exon inclusion) is the preferred motif of
364 muscleblind-like splicing regulator 1 (MBNL1). MBNL1 and RBFOX2 have been found
365 to act synergistically in pluripotent stem cell differentiation⁵⁴ and mesenchymal-specific
366 splicing⁵⁵. The relative abundance of MBNL1's motif UGCUU around alternatively
367 spliced exons was only weakly correlated with the abundance of the GCAUG motif
368 ($r=0.27$), therefore both motifs were likely not in close proximity to each other
369 (Supplementary Figure S6).

370 Surprisingly, we also detected highly enriched poly CU-motifs upstream of included
371 exons, although these are not primary binding sites for RBFOX2. The PTB proteins
372 are known to preferentially bind to these polypyrimidine-rich intronic sequences⁵⁶ and
373 to initiate exon exclusion upon binding⁵⁷. Interestingly, these PTBP motifs were
374 enriched upstream of significantly included exons in our data.

375 To differentiate motifs that are merely abundant around RBFOX2-regulated exons, we
376 analyzed publicly available RBP-RNA interaction data (iClip)⁵². Most of the enriched
377 motifs around alternatively spliced exons upon *Rbfox2*-OE were also confirmed to be
378 bound by RBFOX2 in the iClip data (Figure 5d), specifically the known canonical
379 RBFOX motifs showed high positive z-scores for both data sets. Overall, there was a
380 high correlation between the abundance of motifs around alternatively spliced exons
381 and their presence in iClip peaks (Figure 5e).

393

394 RBFOX2 and PTBP antagonistically shape the transition from NPCs to 395 neurons

396 The occurrence of the PTBP motifs upstream of significantly spliced-in exons upon
397 *Rbfox2* overexpression hints at antagonistic splicing activities of RBFOX2 and PTBP
398 (Figure 6a). Previous studies have indicated that PTBPs bind to pyrimidine-rich
399 sequences located approximately up to 100 nt upstream of alternatively spliced
400 exons^{9,53}. Accordingly, we observed a prominent UCUCU peak in the ~100 nt intronic
401 sequences upstream of exon inclusion events (Figure 6b). Notably, in experiments
402 involving human brain tissue, cell lines, and the mouse cerebral cortex, the upstream
403 occurrence of the PTBP motif was robustly correlated with exon inclusion events. In
404 contrast, in other tissue types, the upstream enrichment of the PTBP motif was
405 associated with exon-skipping^{8,53}.

406 These results raise the question of why a potential upstream PTBP binding leads to
407 exon inclusion rather than the expected exclusion in cells of the nervous system.

408 We thus hypothesized that simultaneous downstream binding of RBFOX2 might
409 antagonistically overrule the splicing outcome of PTBP and therefore favor exon
410 inclusion. This process could contribute to guiding the transition from immature to
411 mature neuronal splicing. Moreover, PTBP1 and PTBP2 are among the high-
412 confidence protein interaction partners of RBFOX2 (Figure 6c). To investigate whether
413 PTBP and RBFOX2 have antagonistic splicing targets, we first examined all significant
414 cassette exon inclusion events (FDR < 0.01, Δ PSI > 0.1) for the co-occurrence of
415 RBFOX and PTBP motifs. We screened for PTBP-motifs upstream and RBFOX-motifs
416 downstream of alternatively spliced exons and for direct RNA-protein binding sites by
417 reanalyzing iClip data from Vuong et al. for PTBP1⁴⁰ and PTBP2⁴⁰ and Jangi et al. for
418 RBFOX2⁵². Roughly 45% of the significant inclusion events (320) had the combination
419 of RBFOX-motif downstream with a PTBP-motif upstream, the majority of these were
420 also highly conserved (Supplementary Figure S7). The cassette exons that were
421 significantly included rarely contained only an RBFOX motif (3) or its binding site (0).
422 The majority of included exons, making up 77.48% (547) of the alternatively spliced
423 exons, harbored either a downstream RBFOX-motif and/or an RBFOX-binding site and
424 simultaneously an upstream PTBP-motif or a PTBP-binding site (Figure 6d). While
425 previous studies have indeed highlighted an interaction between RBFOX and PTBP1
426 specifically^{8,58-61}, the co-regulation of these RBPs may be less relevant in the context
427 of neurodevelopment, as PTBP1 is primarily expressed in non-neuronal cells¹⁷. Thus,
428 we only focused on PTBP2 in our further analyses.

429 To corroborate the RBFOX2/PTBP2 antagonistic splicing regulation of cassette exons,
430 we re-analyzed wildtype and *Ptbp2*-KO data of P1 mouse neocortices⁴⁰. We detected
431 707 significantly alternatively spliced exons in *Ptbp2*-KO (429 included, 187 excluded),
432 with 128 events shared with *Rbfox2*-OE. This represented a 5.241-fold enrichment
433 compared to the expected overlap ($p < 0.0001$, Supplementary Figure 8a). Given the

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

434 proposed antagonistic relationship between both RBPs, we expected *Ptbp2* knockout
435 to induce similar splicing changes as *Rbfox2* overexpression. Indeed, the majority of
436 shared target exons were spliced in the same direction (85.2%, Supplementary Figure
437 8c). Furthermore, we observed a moderate positive correlation between exon inclusion
438 levels in *Ptbp2*-KO and *Rbfox2*-OE samples ($R = 0.2993$, $p < 0.001$, Supplementary
439 Figure 8b). To further investigate the neurodevelopmental relevance of antagonistic
440 splicing, we analyzed the splicing pattern in our data of 230 PTBP2-repressed exons
441 that were reported to be relevant specifically in the context of neocortical
442 development⁴⁰. *Rbfox2*-OE induced alternative splicing in 67 of these PTBP2 targets.
443 Importantly, the majority of the 67 significant events showed exon inclusion (55) and
444 not exon repression in the *Rbfox2*-OE group (Figure 6e, Supplementary Data 5).
445 Among the antagonistically spliced genes was *Ncam1*, encoding for a cell adhesion
446 protein, that showed an abnormal early exon inclusion ($FDR < 0.0001$, $\Delta PSI = 0.148$)
447 in the *Rbfox2*-OE condition which led to an increased presence of the exon18
448 (chr9:49,418,152-49,418,953, Supplementary Figure S5c) producing the NCAM-180
449 isoform. Interestingly, the production of alternative isoforms of NCAM occurs during
450 cortical development between E16.5 and P0. In contrast, NCAM140 and NCAM180
451 are the predominant isoforms for neurons, unlike NPCs that express NCAM120 and
452 NCAM140⁶².
453 Another PTBP2-excluded⁴⁰ and RBFOX2-included cassette exon event was identified
454 in *Kif21b* (chr1:136,101,209-136,101,389, Supplementary Figure S5d). KIF21B is an
455 important regulator of microtubule dynamics. The overexpression of *Rbfox2* induced a
456 highly significant inclusion event ($FDR < 0.0001$, $\Delta PSI = 0.305$).

High-confidence partners are highlighted in light blue d) UpSet plot showing the overlap of the presence of RBFOX or PTBP motifs in the flanking intronic sequences of alternatively spliced cassette exons (400 nt) as well as direct RBFOX2 and PTBP2 binding interactions as indicated by the presence of peaks obtained from iClip data^{40,52} e) Analysis of developmentally regulated cassette exons suppressed by PTBP2 and the overlap with significantly alternatively spliced exons upon *Rbfox2*-OE. The donut-shaped circle represents 230 neurodevelopmentally relevant PTBP2-repressed cassette exon events⁴⁰. Colors indicate regulation of these exons upon *Rbfox2*-OE, blue: unregulated, orange: inclusion, yellow: repression. The lower circle summarizes the presence of conserved binding motifs for RBFOX2 and/or PTBP2 for the exons that are regulated in opposite direction by PTBP2 (repression) and RBFOX2 (inclusion).

471 Furthermore, exonN (chrX:73,284,421-73,284,478) of the *Flna* transcript was
472 significantly included (FDR < 0.05, Δ PSI = 0.213) upon *Rbfox2*-OE (Supplementary
473 Figure S5e). ExonN was specifically repressed in NPCs and included in neurons (FDR
474 < 0.0001, Δ PSI = 0.4) and the exon inclusion was strongly elevated from E14.5 to
475 E16.5 (FDR < 0.0001, Δ PSI = 0.4205). The iClip^{40,52} data also confirmed protein

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

476 binding for RBFOX2, PTBP1, and PTBP2 in flanking sequences of exonN. *Flna* is an
477 important regulator of neuronal migration⁶³ and its splicing by PTBP1 in NPCs is
478 associated with shaping the NPC-to-neuron transition during cortical development^{8,40}.
479 Taken together, our data strongly suggest that RBFOX2 and PTBP2 have antagonistic
480 roles in controlling alternative splicing, specifically affecting transcripts implicated in
481 neuronal differentiation during cortical development. We identified that a significant
482 portion of alternatively spliced cassette exons are excluded upon PTBP2- but included
483 upon RBFOX2-binding in this developmental context.
484

485 miR-92a-3p regulates the expression of *Rbfox2*

486 As we ascertained, NPCs exhibit substantially different splicing patterns compared to
487 neurons (Supplementary Figure S2)^{8,43}. Since RBFOX and PTB proteins seemingly
488 regulated antagonistically an overlapping set of developmentally relevant splice
489 targets, we hypothesized that a cell-type, spatially divergent, and time-specific
490 expression of these splice factors would be necessary for normal cortical development.
491 Indeed, *Ptbp1* and *Ptbp2* transcription peaked at E14.5, but contrary to *Ptbp2*, the
492 *Ptbp1* mRNA abundance decreased in the following developmental stages (Figure 7a,
493 right box). Moreover, *Ptbp1* expression is decreased significantly during the transition
494 from NPCs to neurons (Figure 7a, left box) in accordance with previous reports^{40,56,64}.
495 *Ptbp1* repression is mediated via miR-124-3p, which is a highly specific neuronal
496 miRNA (Figure 7c)^{17,65}. Furthermore, miR-124-3p becomes significantly up-regulated
497 in the transition between E14 and E17 of cortical development (Figure 7c)⁶⁵.
498 In contrast to *Ptbp1* and *Ptbp2*, *Rbfox2* expression was nearly absent in NPCs and
499 increased significantly in neurons (Figure 1a-b, Figure 7a). In a previous study, we
500 identified 36 miRNAs that were expressed in the embryonic cerebral cortex and
501 predicted to target the 3' untranslated region (3' UTR) of *Rbfox2*. By further inspecting
502 these miRNAs, we observed that most of them were upregulated at E14 followed by a
503 significant reduction of expression levels at the subsequent developmental stages E17
504 and P0 (Supplementary Figure S9)⁶⁵. This prompted us to hypothesize that miRNAs
505 might mediate the low expression levels of *Rbfox2* in NPCs. Specifically, miR-92a-3p
506 was identified as a hub microRNA at E14 during cortical development⁶⁵ and it has a
507 predicted binding site in the 3' UTR of *Rbfox2*. Furthermore, the expression of miR-
508 92a-3p was higher in NPCs compared to neurons and decreased gradually from E14
509 to P0 (Figure 7c). Together this data suggests that miRNA-92a-3p might contribute to
510 silencing *Rbfox2* in NPCs at early developmental stages.

511 To follow up on this hypothesis, we performed a luciferase assay using a fragment of
512 the 3' UTR of *Rbfox2* which contained the miR-92a-3p binding site downstream of the
513 *Renilla* luciferase gene. Co-transfection of this reporter plasmid into HEK293 cells
514 together with a miR-92a-3p mimic or a control revealed a reduced luciferase activity of
515 more than two-fold in cells transfected with miR-92a-3p compared to the control. This
516 finding confirmed the gene silencing effect of miR-92a-3p on *Rbfox2* ($p < 0.01$, Figure
517 7d). To investigate the miR-92a-3p-mediated suppression of *Rbfox2* *in vivo*, we
518 electroplated mouse embryos at E14.5 with a miR-92a-3p-silencing construct.
519 Expression of miR-92a-3p was reduced more than 10-fold compared to control
520 samples ($p < 0.0001$, Figure 7e). Following miR-92a-3p reduction, we observed a
521 significantly increased *Rbfox2* expression at E16.5 in the miR-92a knock-down
522 samples compared to the control ($p < 0.01$, fold change = 1.571; Figure 7e). To further
523 corroborate these results, we overexpressed miR-92a-3p in an N2A cell culture. This
524 resulted in a significant increase of miR-92a-3p abundance, as measured by RT-qPCR

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

525 ($p < 0.05$, fold change = 2.442; Figure 7f). Importantly, both the mRNA expression (p
526 < 0.05 , fold change = 0.748 relative to control; Figure 7f) and the protein levels of
527 RBFOX2 ($p < 0.05$, fold change = 0.707 relative to control; Figure 7g,h) were reduced
528 significantly upon miR-92a-3p-overexpression.
529

530 Figure 7 a) Heatmap showing the gene expression of the RBFOX and PTBP protein families in our study, as well
531 as in NPCs and neurons from Liu et al.⁴³ and E14.5 to P30 cortical samples obtained from Weyn-Vanhenyck
532 et al.³⁴. Values correspond to log₁₀-transformed transcripts per million (TPM). b) Expression of miR-124-3p known
533 to repress *Ptbp1* c) Expression of miR-92a-3p predicted to target *Rbfox2*. Data on miRNA expression shown in b
534 and c were obtained from Todorov et al.⁶⁵ d) Luciferase activity in lysates of HEK293 cells transfected with plasmids
535 containing 3' UTR fragments of *Rbfox2* and miR-92a. Fold change of luciferase activity was obtained by calculating
536 the ratio of Renilla luciferase and firefly luciferase activity and then normalizing to the mean of the control. e) In
537 vivo knock-down of miR-92a resulted in a more than 10-fold reduction in miR-92a-3p abundance (left side), and
538 subsequently, *Rbfox2* was 1.5-fold enriched (right side). f) Overexpression of miR-92a-3p in N2A cells led to >2-
539 fold enrichment of miR-92a-3p (left side) and subsequently to a decreased abundance of *Rbfox2* (right side), as
540 measured by RT-qPCR. h) Overexpression of miR-92a-3p in N2A cells reduced the RBFOX2 protein level
541 significantly. g) Representative image of the western blot for RBFOX2 overexpression in N2A cells. h) Schematic

546

547 **Discussion**

548 RBFOX2 is a crucial component of the complex regulatory network that orchestrates
549 cerebral cortical development. We revealed that misexpression leads to a global
550 disruption of the alternative splicing landscape with a significant overrepresentation of
551 high-confidence NDD risk genes. Consequently, aberrant RBFOX2 splicing activities
552 could produce target gene isoforms that lead to impaired brain development and
553 disorders of the central nervous system in humans^{66,67}. For instance, a mutation in
554 *RBFOX2* has been detected previously in a patient with hypoplastic left heart syndrome
555 and NDD²¹. Surprisingly, however, limited research has been conducted on the clinical
556 significance of RBFOX2 as most studies focus on RBFOX1. Mutations in *Rbfox1* have
557 been consistently linked with autism spectrum disorder⁶⁸⁻⁷¹ and susceptibility to
558 epilepsy⁷²⁻⁷⁴. Interestingly, *Rbfox1* knock-out resulted in higher seizure susceptibility⁷⁵,
559 whereas overexpression was also linked with epilepsy and cortex malformation⁷⁶.
560 Furthermore, reduced cytoplasmic RBFOX1 levels in the prefrontal cortex of
561 individuals with schizophrenia²⁴ decrease the stability of *Vamp1*, a schizophrenia-
562 associated gene, in PV⁺ interneurons²⁵. This reduction impairs inhibitory drive from
563 PV⁺ interneurons, contributing to schizophrenia pathogenesis⁷⁷.

564 Though RBFOX1 and RBFOX2 have largely overlapping alternative splicing targets⁴⁹,
565 the divergent expression patterns we observed here and in previous research indicate
566 that both proteins have common but also distinct functions^{23,75,78,79}. To disentangle the
567 specific role of RBFOX2 in the developing brain, we employed an overexpression
568 model instead of a knock-down strategy, as the members of the RBFOX family can
569 compensate for the absence of one of their paralogues²³. Interestingly, early *Rbfox2*-
570 OE caused a premature detachment and migration of neural cells to the IIZ but not
571 further (Figure 4a). This was accompanied by significant splicing events in key
572 components of the Reelin pathway^{44,45}, which plays a crucial role in the migration and
573 localization of cortical neurons and Purkinje cells in the cerebellum. Gehman and
574 colleagues previously showed that the Reelin-binding *Lrp8* gene was alternatively
575 spliced upon *Rbfox2* knock-out. Consequently, Purkinje cells failed to detach and
576 therefore remained near their origin in the VZ²³. Together with our results, this indicates
577 an important role of RBFOX2 in the initiation and control of cell migration in different
578 parts of the developing nervous system.

579 Apart from the altered migration, we also observed impaired neuronal differentiation of
580 *Rbfox2*-overexpressing cells (Figure 4b-d). RBFOX2 was specifically upregulated in
581 the transition from NPCs to newly differentiated neurons (Figure 1e), highlighting its
582 role in neural differentiation. Accordingly, we detected a strong alternative splicing
583 pattern in *Numb* which is a key player in asymmetrical neural stem cell division,
584 determining the cell fate of progenitor cells and neurons⁸⁰. Different isoforms of *Numb*
585 can either promote neuronal differentiation or enhance cell proliferation⁸¹, giving a
586 possible explanation for the observed phenotype of decreased neuronal differentiation
587 in our study.

588 Interestingly, *Rbfox2* expression negatively correlates with expression patterns of the
589 PTBP family. In particular, PTBP1 is a key regulator of non-neuronal splicing in
590 progenitor cells and its repression is required to induce the transition to neurons¹⁷. In
591 contrast, PTBP2, which is reported to be a weaker repressor of alternatively spliced
592 exons than PTBP1^{57,82}, is down-regulated by PTBP1 via poison exon inclusion leading
593 to nonsense-mediated decay^{17,52,64,83}. Remarkably, our data provided compelling
594 evidence for an antagonistic splicing relationship between RBFOX2 and PTBP2.

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

595 Specifically, RBFOX2 and PTBP2 shared a set of targets that undergo alternative
596 splicing during cerebral cortical development (Figure 6d, e). Although PTBP2 typically
597 promotes the exclusion of these antagonistically spliced exons, RBFOX2 induced the
598 opposite effect of exon inclusion. Therefore, the premature overexpression in our
599 experimental set-up likely led to RBFOX2 overruling the splicing program of PTBP2
600 which could explain the aberrant cellular phenotype and altered splicing landscape we
601 observed. Indeed, several targets that are spliced antagonistically between RBFOX2
602 and PTBP2 play crucial roles, for example, in regulating neuronal differentiation
603 (*Flna*)⁸, neurite outgrowth (*Ncam1*), and microtubule dynamics (*Kif21b*). Furthermore,
604 PTBP-recognized motifs are reportedly enriched upstream of alternatively spliced
605 exons that show high inclusion levels in the brain, heart, and skeletal muscles⁵³. These
606 tissues are known expression sites of RBFOX2⁸⁴ with a concurrent low expression of
607 PTBP1⁵³. Therefore, our results and existing reports highlight a complex antagonistic
608 interplay between these proteins in regulating neuronal differentiation^{4,8}. Supporting
609 the concept of such dose-sensitive antagonistic interactions among RNA-binding
610 proteins, Ellis and colleagues recently reported that even a modest increase in RBFOX
611 expression levels was sufficient to alter splicing events dependent on another RBP,
612 MBNL1⁸⁵. Furthermore, RBFOX-concentration-dependent splicing regulation has been
613 described in relation to binding to secondary motifs. Accordingly, high RBFOX2 protein
614 levels during neuronal differentiation can mediate exon inclusion through binding to
615 low-affinity motifs⁸⁶. These findings illustrate how nuanced temporal and spatial RBP
616 expression levels enable cell- and developmental-stage specific gene regulation during
617 brain development.
618 Indeed, several post-transcriptional regulatory mechanisms controlling RBFOX levels
619 have been reported already. For instance, snoRNAs can act as sequestering sites for
620 excess RBFOX2 proteins⁷⁸. Furthermore, RBFOX3 can splice poison exons into
621 *Rbfox2* leading to NMD⁸⁷. Another potential layer of regulation is a putative *Rbfox1*-
622 and *Rbfox2*-specific feedback loop. Accordingly, we observed significantly reduced
623 levels of *Rbfox1* following the overexpression of *Rbfox2* (Figure 2g). Similarly, a knock-
624 out of *Rbfox1* was previously reported to lead to an increased level of RBFOX2⁷⁵ and
625 vice versa²³. Furthermore, both RBFOX1 and RBFOX2 contain RBFOX binding sites
626 near a highly conserved 93-nucleotide exon encoding the second half of the RRM.
627 RBFOX binding leads to exon skipping, thereby resulting in a *Rbfox*ΔRRM isoform with
628 significantly reduced RNA binding affinity⁸⁸. In line with this, the *Rbfox2* overexpression
629 in early-stage cortical cells in our study did not result in a complete splicing switch with
630 all regulated exons being either fully spliced in or spliced out.
631 miRNA binding to 3' UTRs represents another key post-transcriptional regulatory
632 mechanism for controlling gene expression and protein levels. In a study investigating
633 the expression patterns of miRNAs in the embryonic cerebral cortex, we recently
634 highlighted targeting of RNA binding proteins as one of the major processes through
635 which miRNAs impact brain development⁶⁵. Similarly to the reported silencing of *Ptbp1*
636 in neurons via miR-124-3p¹⁷, here we showed for the first time that the NPC hub
637 miRNA 92a-3p suppresses the expression of *Rbfox2* (Figure 7f-h). Conversely,
638 silencing miR-92a-3p in the embryonic neocortex led to a significant *Rbfox2*
639 upregulation (Figure 7e, i). In accordance with our results, miR-92a-3p was previously
640 reported to be enriched in intermediate progenitor cells in humans^{89,90} and,
641 interestingly, differentially expressed in neurodevelopmental and mental disorders. For
642 instance, levels were elevated in blood⁹¹ and serum⁹² of patients with schizophrenia.
643 In contrast, miR-92a-3p was reported to be downregulated in individuals with

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

644 autism^{93,94}. Given the overlapping splicing targets between RBFOX2 and its paralogue
645 RBFOX1, whose mutations have been consistently implicated in such disorders,
646 disruption of the miR-92a-3p/RBFOX2 axis represents an intriguing mechanism for the
647 emergence of diseases of the central nervous system as well as a potential therapeutic
648 target. In particular, future research should focus on elucidating the link between
649 altered miR-92a-3p expression levels and aberrant splicing activities that contribute to
650 disease pathogenesis.

651 Collectively, our results underscore the crucial role of RBFOX2 in the developing
652 cerebral cortex and shed light on the complex interplay with the PTBP family. In our
653 proposed model (Figure 7b), a miRNA-mediated gradual shift from high PTBP levels
654 to a subsequent up-regulation of RBFOX2 shapes neuronal differentiation through a
655 progressive splicing switch from exon exclusion to exon inclusion in commonly
656 regulated targets.

657

658 **Methods**

659 Animals

660 Hes5::GFP mice have been described previously⁹⁵. For *in utero* electroporation, timed
661 mated c57BL6/JRj female mice were purchased on gestation day 12 from Janvier
662 (Janvier Labs, Le Genest-Saint-Isle, France), a certified international breeder. Mice
663 were housed in type II long filter top cages (Tecniplast, Buguggiate, Italy) and kept in
664 a 12 h light/dark cycle in a temperature and humidity-controlled animal room (22 ± 2°C,
665 55 ± 5%). Water and food (ssniff M-Z Extrudat, ssniff, Soest, Germany) were supplied
666 *ad libitum*. Mice were treated according to the protocols approved by the local
667 authorities (Landesuntersuchungsamt Rheinland-Pfalz, license number 23 177-07/G
668 13-1-089).

669

670 Constructs

671 HA-tagged full-length *Rbfox2* was cloned into the XhoI and BglII sites of the pCAGGS-
672 mCherry vector using the following primer combinations: *Rbfox2* 1A full-length forward
673 5'-actgctcgaggccaccatgtaccatcacgtatgcttcagattacgctgcggaaggcggccaggcg-3', with
674 *Rbfox2* reverse 5'-actgagatcttcacgtcacttcagtagg-3'. The miR-92a pre-miRNA
675 including approximately 150 bp of flanking genomic sequence was cloned into the
676 BamHI and EcoRI sites of the pcDNA3.1+ vector using the following primer
677 combinations: miR-92 forward 5'-agtccggtccttagcgttgaaagtggcc-3' with miR-92a
678 reverse 5'-agtccaattctaagttgaggtgtgggtggg-3'. A fragment of the *Rbfox2* 3'UTR
679 containing the miR-92a binding site was cloned into the XbaI site of the pGL3P vector
680 using the following 5'-end phosphorylated oligonucleotides: Sense [Phos] 5'-
681 CTAGACCCCAGTTCATGAGGCCTGGCTATTGCAATATTTACTAGTAGAGGACTC
682 TATAGCT-3', Antisense [Phos] 5'-CTAGAGCTATAGAGTCCTCTACTAGTAAAT
683 ATTGCAATAGCCAGGCCTCATGAACTGGGGT-3'. Sense and Antisense oligos
684 were annealed in annealing buffer (10mM Tris-HCL; pH 7.5; 0.1 M NaCl; 1 mM EDTA)
685 and cloned into the XbaI site of the pGL3P vector.

686

687 Cell Culture, transfections, and luciferase assays

688 N2A and HEK293 cells were cultured in Dulbecco's Modified Eagle Medium (DMEM)
689 with 10% fetal bovine serum as well as 1% Penicillin/Streptomycin. For Luciferase
690 assays, HEK293 cells were seeded on 12-well plates at a density of 90,000 cells per
691 well. Twenty-four hours later, the cells were transfected with 400 ng of the constructs

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

692 cloned into the pGL3P vector, 600 ng miRNA construct and 10 ng pRL-TK vector using
693 the calcium phosphate method. After 48 hours, cells were lysed, and luciferase activity
694 was measured with a CentroXS LB 960 luminometer (Berthold Technologies). N2A
695 cells were transfected with Transfectin reagent (Biorad). The day before the
696 experiment. For transfection, N2A cells were seeded at a density of 250,000 cells per
697 well on 6-well plates. Twenty-four hours later, the cells were transfected with 4000 ng
698 miRNA construct per well. The cells were lysed and processed for RT-qPCR and
699 Westernblot analysis 48 hours after transfection.
700

701 RT-qPCR and Western blot

702 Small RNAs were isolated using the miRNeasy Kit (Qiagen), and total RNA was
703 isolated using the High Pure RNA isolation kit (Roche). TaqMan MicroRNA Assays
704 (Applied Biosystems) were used for miRNA RT-qPCR experiments. The miRNA
705 quantities are relative to U6 snRNA. Total RNA was reverse transcribed using the
706 RevertAid First Strand cDNA Synthesis Kit (Fermentas, Sankt Leon Rot, Germany).
707 For qPCR, SYBR Green Mix was used (TB Green Premix Ex Taq II (RR82WR,
708 Takara)).

709 For Western blot analysis, the cells were lysed, and the proteins were resolved by
710 electrophoresis on SDS acrylamide gels. After transferring the proteins to PVDF
711 membranes, Western blot analyses were performed with antibodies specific for
712 RBFOX2 (rabbit-Anti Rbm9; Bethyl Laboratories) and GAPDH (mouse-Anti GAPDH
713 ab8245, Abcam). Quantification of the bands was performed with ImageJ and
714 normalized to GAPDH band intensity.
715

716 In utero Electroporation

717 For *in utero* electroporation, embryonic day E13.5 pregnant female mice were deeply
718 anesthetized with isoflurane, and the uterine horns were exposed. For overexpression,
719 control or *Rbfox2* expression vectors (4 $\mu\text{g}/\mu\text{l}$) were injected with either pCAG-mCherry
720 or pCAG-eGFP (0.5 $\mu\text{g}/\mu\text{l}$) into the lateral ventricle of each embryo. For electroporation
721 5 pulses of 40 V for a pulse length of 50 ms at 950-ms intervals were applied
722 (Nepagene, Japan). Subsequently, the uterine horns were returned to the abdominal
723 cavity. After 48 h, the mice were sacrificed by cervical dislocation. The embryos were
724 collected and sacrificed by decapitation. For immunostaining experiments, the brains
725 were isolated, fixed in 4% paraformaldehyde, cryoprotected in 15% and 30% Sucrose
726 solutions, embedded in Cryomatrix (Thermo Scientific), and cryosectioned into 20 μm -
727 thick brain slices.

728 For RNA-sequencing, the brain's GFP⁺ area was dissected and digested with trypsin.
729 After stopping the digestion by adding 20% FBS in DMEM and washing with PBS, cells
730 were resuspended in PBS and passed through a 100 μm filter to achieve a single-cell
731 suspension. GFP⁺ cells were then collected by fluorescent activated cell sorting
732 (FACS).
733

734 Immunostaining and Imaging

735 For immunostaining, brain cryosections were fixed in 4% paraformaldehyde (PFA) at
736 room temperature (RT) for 10 minutes. After two washes with PBS, antigen retrieval
737 was performed by incubating the slides in 10 mM sodium citrate with 0.5% Tween-20,
738 pH 6, at 80°C for 20 minutes. Subsequently, the sections were blocked in PBS with

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

739 0.2% Tx-100 containing 2% sheep serum. The sections were then incubated with
740 primary antibody (rabbit anti-RBM9 (Bethyl), mouse anti-RBFOX1 (MABE985,
741 Merck/Millipore, Burlington, MA, USA), rabbit anti-beta III Tubulin (ab18207, Abcam),
742 rabbit Anti-PAX6 (901301, Biolegends), chicken Anti TBR2 (ab34735, Millipore), rabbit
743 Anti-SATB2 (ab34735, Abcam)) in blocking solution overnight at 4°C. The sections
744 were washed three times in PBS 0.2% Tx-100 and incubated in blocking solution
745 containing Alexa-488- or Alexa-594-conjugated secondary antibody (Invitrogen) for 3
746 hours at RT. After three washes in PBS, the sections were embedded in Fluoromount-
747 G with DAPI (00-4959-52, Invitrogen).

748 The sections were viewed using a laser-scanning confocal microscope (LSM710), and
749 images were acquired with the zen software (Zeiss, Oberkochen, Germany). The
750 images were analyzed, and the cells were counted using ImageJ software⁹⁶.

751

752 RNA-sequencing

753 NGS library prep was performed with Clontech SMARTer Ultra Low Input RNA Kit for
754 cDNA generation, followed by NuGEN Ovation Ultralow v2 System for library
755 preparation. Libraries were profiled in a DNA 1000 chip on a 2100 Bioanalyzer (Agilent
756 Technologies) and quantified using the Qubit dsDNA HS Assay Kit, in a Qubit 4.0
757 Fluorometer (Invitrogen by Thermo Fisher Scientific). All six samples were pooled in
758 equimolar ratio and sequenced on an Illumina NextSeq 500/550 device.

759

760 RNA-sequencing analysis

761 The paired-end reads were trimmed using BBDuk (version 39.01)⁹⁷. The trimmed
762 reads were mapped to the Gencode reference genome of *Mus musculus mm39*
763 (released 19.10.2022) using STAR (version 2.7.10b)⁹⁸ and the count per gene and
764 sample was determined using FeatureCounts provided by SubRead (version 2.0.6)⁹⁹.
765 We used DESeq2 (version 1.40.1)¹⁰⁰ in R (version 4.3.0)¹⁰¹ to analyze differentially
766 expressed genes with default settings. Since *Rbfox2* was heavily overexpressed, it
767 was removed from the volcano plot for improved visualization. Genes with an adjusted
768 p-value (Benjamini-Hochberg method) < 0.05 were considered to be differentially
769 expressed.

770 rMATS (version 4.1.2)¹⁰² with default settings was used to detect alternatively spliced
771 genes between the *Rbfox2*-OE and control samples. We did not include novel splice
772 events in our analysis. A splicing event with a false discovery rate (FDR) adjusted p-
773 value < 0.01 and an inclusion level difference $|\Delta\text{PSII}| > 0.1$ was considered significant.
774 Data processing was done with numpy (version 1.23.5)¹⁰³ and pandas (version
775 2.0.1)¹⁰⁴ in Python (version 3.10.12)¹⁰⁵.

776 Plots were generated if not specified otherwise with Matplotlib (version 3.7.1)¹⁰⁶ and
777 seaborn (version 0.12.2)¹⁰⁷.

778 The overlap between significantly alternatively spliced genes and significantly
779 differentially expressed genes was visualized in an UpSet plot (version 0.9.0)¹⁰⁸ using
780 Python (version 3.10.12)¹⁰⁵. Sashimiplots were created using *rmats2sashimiplot* within
781 a Docker container using the image *xinglab/rmats2sashimiplot*. Due to its MISO
782 backend, PSI values may differ from rMATS results.

783

784 Analysis of publicly available transcriptomic data sets

785 We re-analyzed two publicly available data sets to further characterize the alternative
786 splicing landscape during cortical development. The study by Weyn-Vanhentenryck et

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

877 al. contains RNA-sequencing of the mouse cortex from nine-time points (E14.5, E16.5,
878 P0, P4, P30, 4 months, and 21 months). Sequencing files were downloaded from the
879 NCBI Short Read Archive, accession number SRP055008. The study by Liu et al.
880 contains RNA-sequencing from NPCs and neurons purified from mouse cortices at
881 E15.5, sequencing files were obtained from the Gene Expression Omnibus, accession
882 number GSE96950. Furthermore, we re-analyzed transcriptomic data from *Ptbp2*
883 knockout mouse cortices at P1, obtained from the Gene Expression Omnibus
884 (accession number GSE84803)⁴⁰, and triple knockout (*Rbfox1/2/3*) mouse embryonic
885 stem cells, retrieved from the Short Read Archive (accession number SRP128054)³².
886 The sequencing data were processed according to the protocol specified under the
887 section “RNA-sequencing analysis”. The developmental data from Weyn-
888 Vanhentenryck et al. did not allow a pairwise statistical test with rMATS, therefore we
889 conducted a pairwise Fisher’s exact test in scipy (version 1.10.1)¹⁰⁹ for consecutive
890 time points and corrected p-values for multiple comparisons by using Benjamini
891 Hochberg’s procedure with scipy (version 1.10.1)¹⁰⁹. An event was considered
892 significantly developmentally alternatively spliced when two successive time points had
893 an adjusted p-value < 0.01 and $|\Delta\text{PSII}| > 0.1$.
894 We used a Monte Carlo simulation to statistically assess the overlap of alternative
895 splicing events (cassette exons) between *Rbfox2*-OE and either *tRbfox*-KO³² or *Ptbp2*-
896 KO⁴⁰ conditions (see Monte Carlo simulation for details).

897

898 Analysis of publicly available iClip data sets

899 To validate which significant splicing events could be attributable to direct RBFOX2
900 binding, we re-analyzed publicly available iClip data for RBFOX2 expressed in V6.5
901 mESCs. The data was downloaded from NCBI Gene Expression Omnibus, accession
902 number GSE54794⁵². This dataset was supplemented by iClip data for PTBP1 and
903 PTBP2, downloaded from the NCBI short read archive, accession number
904 SRP080878⁴⁰.

905 The iClip data was analyzed in several steps. First, we extracted the unique molecular
906 identifiers from the reads using UMI tools (version 1.1.4)¹¹⁰ and trimmed the adapters
907 with BBDuk (version 39.01)⁹⁷. The trimmed reads were aligned to the reference
908 genome mm39 from Gencode (released 19.10.2022) using STAR (version 2.7.10b)⁹⁸.
909 Following the alignment, we removed PCR duplicates by leveraging the unique
910 molecular identifiers with UMI tools. Crosslinking sites were identified as peaks using
911 Clipper¹¹¹, which was run within a Docker container based on the image
912 brianjee/clipper:61d5456.

913

914 Inferring the alternative splicing trajectory during cortical development

915 We used the SplicePCA tool⁴² integrating our data set with the developmental data of
916 Weyn-Vanhentenryck et al.⁴ and Liu et al.²⁹ to analyze the effect of *Rbfox2*-
917 overexpression on the alternative splicing pattern compared to normal cortical
918 development. We selected events that did not have missing data for any sample and
919 were significantly alternatively spliced in our data and the publicly available data. To
920 investigate how splicing events are correlated with the principal components, we then
921 computed the loading matrix A

922

$$qA = V\sqrt{L}$$

923 where V is the matrix of eigenvectors, L is a diagonal matrix with the corresponding
924 eigenvalues and loadings correspond to correlations between the principal
925 components and the original variables¹¹².

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

836 For each principal component, we then performed a gene set enrichment analysis
837 (GSEA) using the clusterProfiler package (version 4.8.1)^{113,114} in R v4.3.0¹⁰¹ with the
838 biological process ontology, miGSSize of 100, maxGSSize of 500, and an adjusted p-
839 value cut-off of 0.05. The loadings for each gene on the respective principal component
840 were used as input for the GSEA.

841

842 Inferring the direction of exon inclusion

843 We leveraged the NPC and neuron RNA-sequencing data from Liu et al.²⁹ to assess
844 whether Rbfox2-OE is related to a mature (neuronal) or immature (NPC-specific)
845 splicing pattern. By intersecting our significant alternative splicing results with the Liu
846 et al. data set⁴³, we assigned the *Rbfox2*-OE splicing events to three categories: 1)
847 Neuronal direction when the exon inclusion level of the respective gene was
848 significantly higher in neurons than in NPCs in the Liu et al. data; 2) NPC direction
849 when the inclusion level was significantly lower in neurons than in NPC; 3) non-
850 regulated, when the inclusion level was not significantly altered, or the splicing event
851 was not detected in the Liu et al. data set⁴³. The results of this analysis were visualized
852 with a chord diagram using the circlize package (version 0.4.15)¹¹⁵ in R v4.3.0¹⁰¹.

853

854 Motif enrichment analysis

855 We performed a *de novo* motif enrichment analysis to identify enriched motifs in the
856 intronic regions located upstream and downstream of alternatively spliced exons. The
857 intronic sequences around alternatively spliced exons (enriched and suppressed
858 exons separately) and a set of background sequences that were not alternatively
859 spliced (FDR > 0.8 and Δ PSII < 0.1) were loaded from the mm39 reference genome
860 (Gencode released 19.10.2022) using pysam (version 0.21)¹¹⁶.

861 All possible pentameric sequences and their occurrence in the up- and downstream
862 intronic sequences were counted in a sliding window of 50 nt. For each motif, we then
863 subtracted its occurrence in the respective background sequences. Next, motif
864 frequencies were transformed to z-scores using scipy (version 1.10.1)¹⁰⁹. A motif was
865 considered to be enriched when it had a z-score > 4 ($p < 0.0001$, two-sided z-test).

866 The iClip peaks were used to validate these predicted motifs. We again screened for
867 the occurrence of every possible pentameric sequence within the peaks of RBFOX2
868 and the control, subsequently subtracted the respective values, and performed z-
869 scoring. Next, the z-scores of the iClip and RNA-Sequencing motif enrichment analysis
870 were correlated using scipy (version 1.10.1)¹⁰⁹.

871

872 Motif co-occurrence analysis

873 The co-occurrence of motifs was analyzed similarly to the motif enrichment analysis.
874 400 nt of intronic sequence flanking the alternatively spliced exon or the exon itself
875 was loaded with pysam (version 0.21.0)¹¹⁶ and screened for the presence of a PTBP-
876 associated CU-rich motifs (UCUCU, UUUCU, UCUUU, CUCUC, UCUCC, CUCUU,
877 UUCUU)¹¹⁷ with a z-score > 4 upstream and RBFOX2 canonical motif downstream
878 (GCAUG, UGCAU, CAUGC). Moreover, we integrated confirmed binding sites from
879 the iClip data for RBFOX2⁵², PTBP1⁴⁰, and PTBP2⁴⁰. We visualized this using an
880 UpSet plot (version 0.9.0)¹⁰⁸ using Python (version 3.10.12)¹⁰⁵. and only included
881 overlapping sets with a minimum size of 1.

882 Further, we examined evolutionarily conserved motif occurrences around these exons
883 by filtering for motifs with a phastcons 35-way¹¹⁸ score > 0.8.

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

884

885 Motif localization map

886 Next, we mapped the localization of the enriched motifs identified in the previous
887 analysis on the alternatively spliced exon and the flanking exons. To the end, we
888 computed the motif density in a sliding window of 50 bp for all up- and downregulated
889 events and background (non-regulated events). Motif density corresponds to the
890 fraction of the 50 nt sliding window that is covered by the motif. The estimates were
891 corrected by subtracting the background density for each motif. This analysis was
892 limited to 150 nt of exonic and 400 nt of intronic sequences spanning up- and
893 downstream from the intron/exon boundaries.

894

895 STRING network analysis

896 Potential interaction partners of RBFOX2 were identified with STRING using all
897 potential interaction sources (version 12.0 beta)¹¹⁹, allowing 20 interacting proteins
898 and showing confidence as edges. Interactions with RBFOX2 with a confidence score
899 higher than 0.7 were considered high-confidence.

900

901 Statistical analysis of immunohistochemistry data

902 Two groups were compared statistically using a t-test or a Wilcoxon test when
903 assumptions of the parametric test were violated, and a data transformation did not
904 improve the model fit. More than two groups were analyzed using one-way or two-way
905 analysis of variance followed by Tukey's post hoc test or post hoc comparison of model
906 means. Data were transformed using a \log_e or an arcsine square root transformation
907 when assumptions of normality and homogeneity of variance were violated. All p-
908 values are two-tailed and a p-value < 0.05 was considered statistically significant.
909 Statistical analysis was performed using R v4.2.2¹⁰¹ or Python (version 3.10.12)¹⁰⁵
910 using scipy (version 1.10.1)¹⁰⁹.

911

912 Overlap of alternatively spliced genes with NDD risk genes

913 Alternatively spliced genes were intersected with high-confidence NDD genes from the
914 GeneTrek database v33³³ to calculate the observed overlap. To obtain a null
915 distribution of the expected overlap, 1317 genes (equal to the total number of
916 alternatively spliced genes upon *Rbfox2*-OE) were randomly sampled from the
917 universe of genes with annotated splice events and the overlap with high-confidence
918 NDD genes and the p-value computed (see Monte Carlo Simulation section for details).

919

920 Monte Carlo Simulation

921 Monte Carlo simulations were performed to evaluate the statistical significance of
922 overlaps for various splicing events and genes. In each simulation, a number of genes
923 equal to the observed count of alternatively splicing events (*tRbfox*-KO and *Ptbp2*-KO)
924 or genes (NDD risk genes) were randomly sampled from the universe of genes or
925 splicing events. The overlap with the gene set of interest (e.g., high-confidence NDD
926 genes) was then calculated. This process was repeated 100,000 times using a seed
927 of 42 to generate a null distribution of expected overlaps. The p-value was calculated
928 as

bioRxiv preprint doi: <https://doi.org/10.1101/2024.09.20.614071>; this version posted October 22, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. All rights reserved. No reuse allowed without permission.

929
$$p = 2 * (1 - CDF(zscore))$$

930 using Python (version 3.10.12)¹⁰⁵, numpy (version 1.23.5)¹⁰³, and scipy (version
931 1.10.1)¹⁰⁹. CDF corresponds to the cumulative distribution function of the normal
932 distribution.

933

934 **Data availability**

935 The RNA Sequencing data generated for this study are available on NCBI SRA
936 (Sequence Read Archive) under the accession number PRJNA1013323.

Supplemental Figures

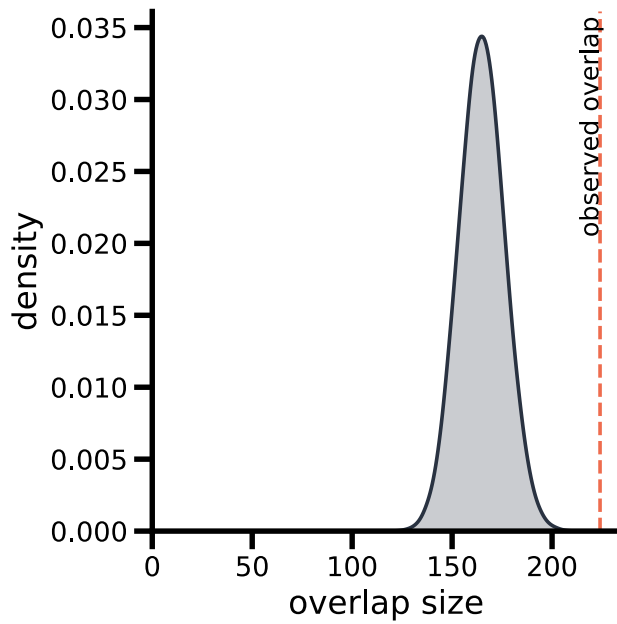

Supplementary Figure 1 a) Volcano plot showing minimal alteration in differential gene expression upon Rbfox2-overexpression (Rbfox2-OE) in the embryonic neocortex compared to control samples b) Top 50 differentially expressed genes. Expression values are shown as z-scores.

Supplementary Figure 2 Developmentally regulated splicing events^{1,2} hierarchically clustered using the percentage spliced-in (PSI) values. Embryonic and neuronal maturation stages cluster together. Clearly, Rbfox2-OE leads to an aberrant splicing pattern that does not cluster with samples from comparable developmental stages.

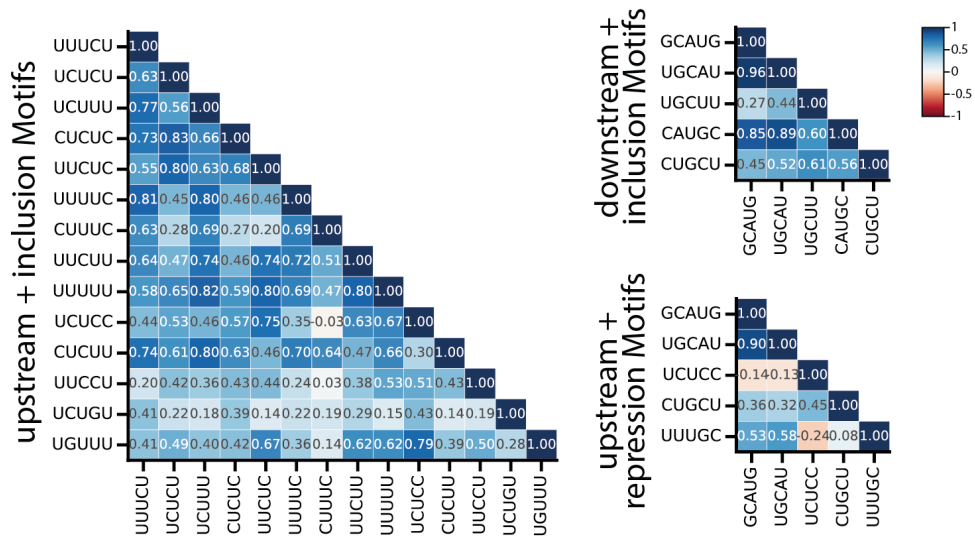

Supplementary Figure 3 Comparison of splicing changes in *Rbfox2* overexpression (OE) and *Rbfox* triple knockout (tKO) conditions in mouse embryonic stem cells (data from Jacko et al.)³. a) Correlation analysis of splicing changes (ΔPSI) between *Rbfox2*-OE and *tRbfox*-KO conditions. Each point represents a significant splicing event detected in both data sets. The x-axis shows ΔPSI values for tRBFOX-KO, while the y-axis shows ΔPSI values for *Rbfox2*-OE. A strong negative correlation ($R = -0.6624$, $p < 0.0001$) confirms the expected opposite splicing effects in OE versus KO conditions. b) Monte Carlo simulation results from 100,000 runs, showing the distribution of overlap sizes between *Rbfox2*-OE and tRBFOX-KO splicing events. The x-axis represents the overlap size, and the y-axis shows the density of occurrences. The observed overlap (indicated by the orange dashed line) is significantly larger than expected by chance (fold change ≈ 9.833 , $p < 0.0001$).

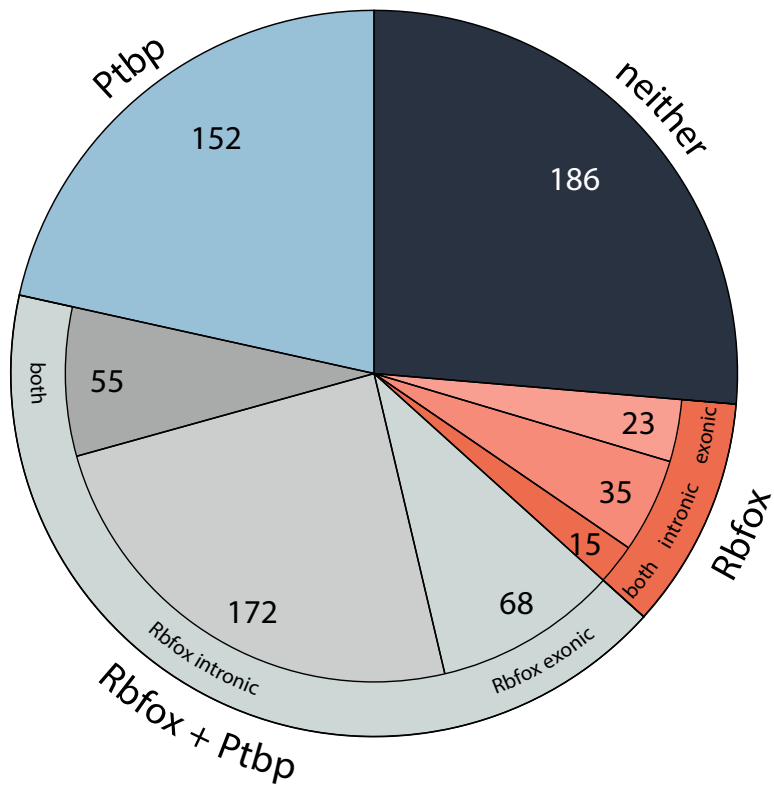

Supplementary Figure 4 Monte Carlo simulation results from 100,000 runs, showing the overlap distribution between randomly selected genes and high-confidence neurodevelopmental disorder (NDD) genes⁴. The observed overlap between significantly alternatively spliced genes and NDD genes is significantly enriched (224 out of 1317 genes, fold change ≈ 1.358 , $p < 2e-07$, Supplementary data 5))

Supplementary Figure 5 Alternative splicing analysis of seven genes during development and upon Rbfox2 overexpression. (a-g) Each panel shows a different gene (Ap2a1, Clasp2, Ncam1, Kif21b, Flna, Lrp8, Vldlr) with bar graphs displaying percentage spliced-in (PSI) values across developmental stages and conditions (top), sashimi plots illustrating read coverage and junction reads (middle), and alternative isoforms from the GFF annotation file (bottom). Bar graphs include control, Rbfox2-OE, embryonic and postnatal stages, NPCs, and neurons. Sashimi plots show three replicates for two conditions (control: blue, Rbfox2-OE: orange).

Supplementary Figure 6 Correlation of motif occurrences for upstream inclusion events, downstream inclusion events, and downstream repression events of Rbfox2-overexpression samples compared to control.

Supplementary Figure 7 Analysis of significantly alternatively spliced cassette exons for conserved PTBP and RBFOX motifs.

Supplementary Figure 8 Comparison of splicing changes in Rbfox2-OE and Ptbp2-KO⁵ conditions. a) Monte Carlo simulation results from 100,000 runs, showing the distribution of overlap sizes between randomly selected events and those affected by Rbfox2-OE and Ptbp2-KO. The x-axis represents the overlap size, and the y-axis shows the density of occurrences. The observed overlap (indicated by the red dashed line) is significantly larger than expected by chance, suggesting a substantial and non-random relationship between Rbfox2-OE and Ptbp2-KO splicing effects. b) Correlation analysis of splicing changes (ΔPSI) between Rbfox2-OE and Ptbp2-KO. Each point represents a splicing event. The x-axis shows ΔPSI values for Ptbp2-KO, while the y-axis shows ΔPSI values for Rbfox2-OE. A moderate, statistically significant positive correlation ($R = 0.2993$, $p < 0.001$) is observed, indicating a degree of similarity in splicing effects between the two conditions. c) Intersection analysis of splicing events affected by Ptbp2-KO and Rbfox2-OE. The upsetplot shows the percentages of cassette exons that are included (inc) or skipped (skip) in both conditions. The majority (85.2%) of events show increased inclusion in both Ptbp2-KO and Rbfox2-OE.

Supplementary Figure 9 Heatmap showing the expression of miRNAs predicted to target *Rbfox2*. Normalized expression values are shown as z-scores. Data were obtained from Todorov et al.⁶.

Stage-specific expression patterns and co-targeting relationships among miRNAs in the developing mouse cerebral cortex

Hristo Todorov¹, Stephan Weißbach^{1,2}, Laura Schlichtholz^{1,3}, Hanna Mueller¹, Dewi Hartwich¹, Susanne Gerber¹ & Jennifer Winter¹

microRNAs are crucial regulators of brain development, however, miRNA regulatory networks are not sufficiently well characterized. By performing small RNA-seq of the mouse embryonic cortex at E14, E17, and P0 as well as in neural progenitor cells and neurons, here we detected clusters of miRNAs that were co-regulated at distinct developmental stages. miRNAs such as miR-92a/b acted as hubs during early, and miR-124 and miR-137 during late neurogenesis. Notably, validated targets of P0 hub miRNAs were enriched for downregulated genes related to stem cell proliferation, negative regulation of neuronal differentiation and RNA splicing, among others, suggesting that miRNAs are particularly important for modulating transcriptional programs of crucial factors that guide the switch to neuronal differentiation. As most genes contain binding sites for more than one miRNA, we furthermore constructed a co-targeting network where numerous miRNAs shared more targets than expected by chance. Using luciferase reporter assays, we demonstrated that simultaneous binding of miRNA pairs to neurodevelopmentally relevant genes exerted an enhanced transcriptional silencing effect compared to single miRNAs. Taken together, we provide a comprehensive resource of miRNA longitudinal expression changes during murine corticogenesis. Furthermore, we highlight several potential mechanisms through which miRNA regulatory networks can shape embryonic brain development.

Mammalian brain development is an extraordinarily complex process where neural progenitor cells proliferate and give rise to all neuronal and glial cell types. Numerous transcriptional, post-transcriptional, and epigenetic mechanisms integrate with each other to control progenitor proliferation and self-renewal, differentiation, and lineage commitment as well as migration in a strictly spatio-temporal manner. One of the key regulators of these processes are microRNAs (miRNAs). In most cases, these small RNAs bind to their target mRNAs' 3'- untranslated region (3'UTR) to induce mRNA degradation or translational inhibition. In the canonical pathway, miRNA genes are transcribed into a pri-miRNA in the cell nucleus by PolII/III^{1,2}. In subsequent processing steps, the pri-miRNA is cleaved into a hairpin pre-miRNA by the microprocessor complex Drosha-Dgcr8 and transported to the cytoplasm by Exportin-5³⁻⁶. In the cytoplasm, the pre-miRNA is bound and cleaved by a complex containing the RNase Dicer1 to form the mature miRNA duplex⁷. From this duplex, the functional strand is loaded into the RISC complex,

guiding it to the 3'UTR's target site⁸. Mice carrying conditional *Dicer* gene deletions in the embryonic telencephalon have shown a variety of phenotypes in the cerebral cortex, such as reduced cell proliferation and impaired neuronal differentiation, increased apoptosis, defective cortical layering and microcephaly⁹⁻¹⁴.

In the brain, 70% of all miRNAs are expressed, most of them in a highly cell-type- and developmental-time-specific manner¹⁵. Given that the total number of human miRNAs is estimated to be ~2300, at least 1600 different miRNAs may be expressed in the brain¹⁶. While this suggests that miRNA regulation is generally important for brain development and function, the specific functions of most miRNAs remain unknown. Single miRNAs are involved in some of these processes including, for example, cell proliferation (e.g., let-7, miR-124, miR-9), neuronal differentiation (e.g., let-7, miR-124, miR-9, miR-128) and migration (e.g., miR-9, miR-124, miR-379-410)^{17,18}. Many of the functionally studied miRNAs are among the most highly expressed in the brain such as miR-9, miR-124 and let-7¹⁷. Most miRNAs

Article

typically have a relatively weak effect on their target genes^{19,20}. Previous research has suggested that the regulatory potential of a given miRNA could be enhanced by cooperating with other miRNAs in co-targeting networks²¹. This hypothesis is supported by the fact that most 3'UTRs contain more than one miRNA binding site and most miRNAs have matching binding sites in up to several hundred 3'UTRs. A network of miRNAs co-operatively binding at distinct 3'UTR positions can potentially enhance target gene repression by additive or synergistic effects^{22,23}. MiRNA binding at closely spaced binding sites (~15–35 nt) can further enhance the repressive effect^{23–25}. We and others have previously identified mRNAs that are targeted by several miRNAs leading to a synergistic or additive repressive effect^{19,20,26}. For example, miRNAs of the miR-379-410 cluster regulate neurogenesis by targeting multiple miRNA binding sites in the N-cadherin 3'UTR in an additive manner¹⁹. While this highlights the regulatory potential of such miRNA networks during brain development, their detailed composition and temporal dynamics remain poorly characterized. Using an unbiased bioinformatics approach to identify co-targeting networks in mouse tissues, Cherone and colleagues recently found that miRNAs enriched in the human prefrontal cortex had more co-targeting partners than those enriched in other tissues suggesting that miRNA co-targeting is especially important in the brain²⁰.

In the current study, we employed high-throughput small RNA sequencing of the mouse cerebral cortex to create a detailed map of miRNA expression patterns and their longitudinal dynamics at key developmental stages. Using miRNAs whose expression was significantly correlated with developmental time, we constructed a comprehensive co-targeting network in which miRNAs with higher expression levels were associated with significantly more co-targeting relationships. In luciferase assays, we validated the enhanced gene silencing effect of cooperative miRNA binding in a set of target genes involved in the regulation of nervous system development.

Results

Temporal dynamics of miRNA expression during cerebral cortex development

To study the expression patterns of miRNAs during mammalian corticogenesis, we performed small bulk RNA sequencing in both female and male mice at a progenitor-dominated developmental phase (embryonic day E14), at an intermediate time point (E17) and at birth (postnatal day P0) when neurons from all six layers of the neocortex have been born^{27,28} (Fig. 1). Using stringent filtering criteria for expression levels (>10 CPM in at least five samples), we detected a total of 489 miRNAs with only 13 of those corresponding to novel miRNAs. In agreement with previous reports^{17,29}, miR-9, members of the let-7 family, miR-128, and miR-124 were among the top 20 most abundantly expressed miRNAs in the developing cerebral cortex (Supplementary Fig. 1). Principal component analysis (PCA) revealed a distinct separation of samples according to their developmental stage. However, E17 and P0 samples had a more similar global expression pattern to each other compared to E14 (Fig. 2a). Since we did not observe apparent differences related to sex, female and male samples were processed together in the subsequent analyses.

We detected the highest number of differentially expressed miRNAs at the E14 vs. P0 time points, where 169 miRNAs were up- and 172 were down-regulated (Fig. 2b–f, Supplementary data 1). However, the major transcriptional shift already occurred in the transition from E14 to E17, where ~57% of all detected miRNAs significantly changed their expression level (122 up- and 144 down-regulated miRNAs). In contrast, only 36% of all detected miRNAs were differentially expressed in E17 vs. P0 samples (82 upregulated and 93 downregulated miRNAs). Interestingly, a higher number of miRNAs were consistently downregulated at earlier developmental time-points in all pairwise comparisons (45 vs. 32 upregulated miRNAs, Fig. 2b, c, g).

To study the expression of miRNAs specifically during neurogenesis, we isolated NPCs from the cortices of mouse embryos at E14 and differentiated them in vitro into neurons. Small RNA sequencing of these cells

Fig. 1 | Schematic representation of the study. To investigate the expression patterns of miRNAs during cerebral cortical development in the mouse, we performed RNA-seq of bulk tissue at E14, E17 and P0 as well as in NPCs isolated from the cerebral cortex and differentiated into neurons. Subsequently, we employed weighted gene co-expression network analysis (WGCNA) to identify modules of co-expressed miRNAs. We then constructed a network of miRNAs sharing more target genes than expected by chance. Co-targeting relationships between selected miRNAs were validated using luciferase reporter assays, demonstrating enhanced gene silencing effect on neurodevelopmentally-relevant genes for combinations of miRNAs compared to individual miRNAs.

Article

Fig. 2 | Expression changes of miRNAs during mouse cerebral cortex development. **a** Principal component analysis of bulk small RNA sequencing samples from the cerebral cortex of female and male mice at different developmental stages. $n = 4$ biological replicates for females at E14, $n = 6$ in all remaining groups. **b** Venn-diagram of upregulated miRNAs at earlier compared to later stages of cortical development. **c** Venn-diagram of downregulated miRNAs at earlier compared to

later developmental stages. **d-f** Volcano plots of differentially expressed miRNAs. Positive log₂ fold changes indicate miRNAs upregulated at earlier compared to later developmental stages in each pairwise comparison (E14 vs. E17, E14 vs. P0 and E17 vs. P0). **g** Heatmap of miRNAs differentially expressed in each pairwise comparison of different developmental stages. Mean expression values per developmental stage are shown as z-scores.

revealed 110 miRNAs that were upregulated and 113 miRNAs that were downregulated in NPCs compared to neurons, respectively. miR-124-3p and miR-369-3p were the most significantly upregulated miRNA in neurons, whereas miR-155-3p and miR-34b-3p were the most significantly upregulated miRNAs in NPCs (Supplementary Fig. 2a, d, Supplementary data 1). 66% of the upregulated (72 out of 110) and 65% of the downregulated (73 out of 113) miRNAs in NPCs vs. neurons were also differentially expressed in the comparison of bulk samples from E14 vs. P0, confirming the replicability of the expression patterns we observed (Supplementary Fig. 2b-d). Interestingly, these overlapping miRNAs corresponded to 43% of all upregulated and 42% of the downregulated miRNAs in E14 vs. P0, suggesting that a large proportion of the differentially regulated miRNAs might be attributable to the non-neuronal cells in the bulk samples. This observation is plausible, as gliogenesis takes place roughly between E17 and P0 of cortical development^{28,30} therefore the bulk samples

from P0 likely contained both neuronal and non-neuronal cell types. In agreement, several of the developmental-stage-dependent expression changes we observed align with previously reported roles of miRNAs in inhibiting or promoting gliogenesis. For instance, miR-106a-5p was upregulated at E14 compared to E17 and P0 (Fig. 2g). miR-106a was previously reported to suppress gliogenic differentiation of neural stem cells and induce neurogenic cell fate commitment³¹, which fits well with the upregulation of expression during peak neurogenesis in our study. Furthermore, we observed an upregulation of the gliogenic miR-338³² specifically at P0 but not in neurons compared to NPCs (Supplementary data 1), thus underscoring the potential role of this miRNA specifically in promoting differentiation of glia cells. As another example, miR-153 whose inhibition was shown to confer gliogenic competence to neural stem cells³³, was upregulated in neurons compared to NPCs in our analysis (Supplementary data 1).

Fig. 3 | Weighted miRNA co-expression analysis. Weighted gene co-expression network analysis identifies sets of co-regulated miRNAs during the development of the cerebral cortex

Next, we applied weighted gene co-expression network analysis (WGCNA) to construct networks of co-expressed miRNAs and better characterize their transcriptional dynamics along the cortical developmental trajectory (Fig. 1). We obtained 18 modules that were assigned to arbitrary colors (Fig. 3a, detailed information of the specific miRNAs included in each WGCNA module is included in Supplementary data 2). Module eigengenes (MEs) that correspond to the first dimension in a principal component analysis of the expression matrix of the corresponding WGCNA module, served as proxies for the characteristic transcriptomic signature of each module. Six MEs were significantly negatively correlated with the developmental time point indicating that the miRNAs in the respective modules showed overall reduced expression levels at later compared to earlier developmental stages (Fig. 3b). In contrast, four modules contained miRNAs whose eigengene expression significantly increased during brain

development. The black module, which contained the highest number of miRNAs (139), had the strongest negative correlation with the developmental stage. The overall expression pattern captured by the ME, indicated that the black module contained miRNAs whose expression level peaked at E14 and dropped at E17, remaining stable afterwards (Fig. 3c). The green module was the second largest, containing 101 miRNAs with generally linearly increasing expression levels from E14 to P0 (Fig. 3d). Remarkably, although these two modules were regulated in opposite directions, they shared most of their targets (6244 common targets, corresponding to 79% of all black module and 72% of all green module targets, Supplementary Fig. 3c). Gene ontology analysis using the genes targeted by the miRNAs revealed that both the black and the green modules are involved in the regulation of key nervous system developmental processes such as axon development and guidance, neuron projection, dendrite development, and synapse organization (Fig. 3e, f, Supplementary data 3).

To identify key miRNAs at early and late embryonic brain developmental stages, we reconstructed the network structure of miRNAs within

the black and green modules and identified key driver (hub) miRNAs as described previously^{34,35}. The black module contained 21 hub miRNAs. 12 miRNAs were also upregulated in NPCs compared to neurons including members of the miR-92 family - miR-92a, miR-92b (Fig. 4c). Moreover, we detected 18 key driver miRNAs in the green module. Ten of these were also significantly upregulated in neurons compared to NPCs, including the

neuron-specific miR-124 and miR-137 (Fig. 4d). This analysis confirmed the stage-specific regulation of a core set of miRNAs during embryonic cortical development.

Importantly, all hub miRNAs in the green module and all but one miRNA in the black module were significantly differentially regulated at E14 compared to the P0 developmental stage (Fig. 4a, b). Furthermore, hub

Article

Fig. 4 | Hub miRNAs in the black and green WGCNA modules. Network plot showing the hub miRNAs in the black (a) and green (b) modules. Hub miRNAs are represented as bigger nodes. Purple halos around the nodes indicate miRNAs that are significantly differentially expressed between E14 and P0. Differential expression of hub miRNAs from the black (c) and green (d) module detected in the NPCs versus neurons analysis. Positive log₂ fold changes indicate an upregulation in NPCs, negative values correspond to upregulation in neurons. White bars indicate non-significant fold changes. e Distribution of differentially expressed genes in the mouse cerebral cortex between E14.5 and P0. The overall number of genes as well as the

number of these genes that are validated targets from miRNAs in the black and green module as obtained from miRTarBase are given. The comparison of the distribution of differentially expressed targets of the black or green module from the overall distribution of differentially expressed genes was performed with a Fisher's exact test. f Z-score transformed average expression of selected validated targets of miRNAs from the green module that are significantly upregulated at E14.5 compared to P0. The expression values in (e) and (f) were obtained from the bulk RNA-seq of the mouse cerebral cortex across development study by Weyn-Vanhentenryck et al.³⁷.

miRNAs in both the black and the green modules showed significantly stronger module membership and gene trait significance estimates compared to the remaining miRNAs in the respective module (Supplementary Fig. 3e–h), thereby confirming their importance. Here, module membership corresponds to the correlation between the miRNA's expression and the module eigengene. Furthermore, the gene trait significance represents the correlation between miRNA expression and the trait of interest, in our study—the developmental stage³⁶.

To gain an insight into the relevance of hub miRNAs in regulating target gene expression across development, we re-analyzed bulk RNA-seq data from the mouse cortex at E14.5, E16.5, and P0 from the study by Weyn-Vanhentenryck and colleagues³⁷. We limited this analysis to the experimentally validated targets of the conserved hub miRNAs that we obtained from miRTarBase³⁸. We did not observe a significant deviation in the differential expression of target genes of the black module when comparing P0 and E14.5 (Fig. 4e). This could likely be explained by the overall lower number of validated targets for conserved key driver miRNAs from the black module (Supplementary Fig. 3d). However, the number of downregulated targets of the green module's hub miRNAs was significantly higher compared to the overall background distribution of differentially expressed genes (Fig. 4e). The increased proportion of genes with a reduced expression at the time point when the green module's hub miRNAs that target them have their expression peak strongly suggests that these miRNAs are involved in repressing these targets' expression *in vivo*.

To gain insight into the biological processes that the downregulated targets of green module hub miRNAs are involved in, we performed a GO annotation analysis (Fig. 4f). Notably, many of these genes are associated with the cell cycle, stem cell maintenance and proliferation (e.g., the transcription factors *Sox2*, *Sox9* and *Sox11*), cell fate commitment (e.g., *Neurog2*), and negative regulation of neuronal differentiation. Furthermore, several targets are involved in activating the Notch signaling pathway (e.g., *Notch1*, *Notch3*) and negatively regulating the Wnt pathway. Important mediators of RNA splicing (e.g., the RNA binding proteins *Ptbp1* and *Ptbp2*) were also among the downregulated targets. Notably, the green module hub miR-124-3p is known to repress *Ptbp1* expression and thereby induce neuron-specific alternative splicing programs required for neuronal differentiation³⁹. Therefore, these results indicate that miRNAs might be particularly important for the switch from undifferentiated NPCs to differentiated neurons by silencing the expression of key factors that promote stem cell maintenance, proliferation and non-neuronal splicing patterns.

Prediction of miRNA co-targeting networks in the developing cerebral cortex

WGCNA revealed that clusters containing multiple miRNAs are co-expressed during cortical development. Furthermore, when looking at the predicted targets of the black and green modules, we observed that only ~30% were potentially targeted merely by a single miRNA. On average, each gene was associated with more than 3 miRNAs (Supplementary Fig. 3a, b). This apparent redundancy of simultaneously expressed miRNAs that putatively bind to overlapping sets of genes supports the previously proposed hypothesis that miRNAs might act together to co-operatively exert stronger gene silencing (Fig. 1). To construct a comprehensive co-targeting

network of miRNAs in the developing cerebral cortex, we designed a statistical framework that allowed us to detect which miRNAs share significantly more targets than expected by chance. In this analysis, we included all miRNAs whose module eigengene was correlated significantly with developmental time in the WGCNA (Fig. 3b). Furthermore, we only considered conserved miRNAs with at least 300 conserved targets and distinct seed sequences²⁰. miRNAs belonging to the same broad conserved family and thereby having identical seed sequences, were grouped together for the statistical testing. After applying these filtering criteria, we performed the co-targeting prediction with a set of 77 miRNA families corresponding to 106 individual miRNAs (Fig. 5a). We detected 1216 significant co-targeting pairs with an adjusted *p*-value < 0.05 (Fig. 6, Supplementary data 4) and each miRNA had on average 41 co-targeting relationships (Fig. 5b). Interestingly, the number of significant co-targeting relationships was positively correlated with the miRNA's average expression level (Fig. 5c). This finding implies that important miRNAs might need to be produced at higher amounts to facilitate their involvement in multiple cooperative gene silencing interactions in the co-targeting network. Importantly, hub miRNAs such as miR-92a/b from the black module as well as miR-124 and miR-137 from the green module were among the miRNAs with the highest expression level and highest number of co-targeting relationships (Fig. 5c) indicating that these miRNAs might be master regulators in both co-expression and multi-targeting networks. As expected, the length of the 3' UTR was positively correlated with the number of significant miRNA pairs targeting a gene (Fig. 5d). Interestingly, *Nova1*, was among the top 10 genes involved in the highest number of co-targeting associations. NOVA1 is a neuron-specific splice factor that is crucial for neuronal viability⁴⁰ and regulates the alternative splicing of genes involved in synapse formation⁴¹. In line with this, we detected a significant *Nova1* expression increase in cortical samples at P0 compared to E14.5 (log₂ fold change = 0.84, adj. *p*-value < 0.0001) when re-analyzing the RNA-seq data from Weyn-Vanhentenryck et al.³⁷. Thus, our findings further highlight the potential importance of miRNAs in regulating neurodevelopment by influencing the expression of crucial effectors of alternative splicing processes.

Remarkably, we detected the strongest co-targeting relationship between miR-137 and the miR-25/miR-363/miR-92 family, sharing 353 common gene targets (Fig. 5f). While miR-137 was upregulated at later developmental stages, all members of the miR-25/miR-363/miR-92 cluster were regulated in the opposite direction. This prominent association between hub miRNAs, that were not co-expressed, prompted us to investigate the distribution of intra-modular (between miRNAs from the same module) and inter-modular (miRNAs from different modules) co-targeting relationships for the black and green WGCNA modules. While we expected that relationships between co-expressed miRNAs might be enriched, we indeed observed a comparable distribution of intra- and inter-modular co-targeting pairs (Fig. 5e). These findings point to two distinct potential regulatory mechanisms justifying the need for miRNAs to share significantly more targets than expected by chance. On the one hand, miRNAs with common targets regulated in opposite directions during cortical development might arise from the need to facilitate target gene regulation at different time points or in distinct cell types. On the other hand, co-expressed miRNAs that regulate the same genes could cooperatively bind to their targets to exert a stronger repressive effect compared to single miRNAs.

Enhanced gene silencing effect by cooperative binding of co-expressed miRNAs

To validate the hypothesis that co-expressed miRNAs bind cooperatively to their common targets to enhance their repressive effect, we employed luciferase reporter assays focusing on miRNAs that were upregulated during embryonic brain development. We performed a

gene ontology term look-up of all targets and filtered potential candidate genes for terms including brain/forebrain development and (central) nervous system development. Then we looked for genes with two or more conserved binding sites in their 3' UTR for miRNAs upregulated during cortical development. Using this strategy, we compiled a list of 7 candidate target genes (*Neurod1*, *Apc*, *Dcx*, *Ndst1*,

Article

Fig. 7 | Luciferase activity in lysates of HEK293 cells transfected with plasmids containing 3' UTR fragments of target genes. a–d Lysates were co-transfected with different combinations of miRNA mimics. Fold change (FC) of luciferase activity was obtained by calculating the ratio of *Renilla* luciferase and firefly luciferase activity and then normalizing to the mean of the control siRNA or miRNA group. Locations of the binding sites in the 3' UTR of the respective gene are represented by colored dots. The length of the 3' UTRs is indicated in kbp. e–h Fold change of luciferase activity was measured after introducing point mutations in the binding sites of the miRNAs in the 3' UTR regions. Colored dots on the x-axis indicate that the binding site of the respective miRNA was intact, gray dots indicate a mutated

binding site. i–k Expression of miRNAs and target genes during embryonic brain development. Expression values were normalized to a 0–1 range. miRNA expression was quantified by bulk RNA-seq of the mouse cerebral cortex at E14, E16.5 and P0. Target gene expression values were measured at E14.5, E16.5 and P0 and were obtained from the bulk RNA-seq study of the mouse cerebral cortex at different developmental stages by Weyn-Vanhenryck et al.³⁷ Data are shown as mean \pm standard error of the mean and individual values. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, two-way analysis of variance followed by Tukey's post-hoc test. $N = 12$ replicates in (a) and (c), $n = 18$ in d, $n = 9$ in (b), (c) and (e–h), $n = 2$ in (i–k).

vector, which also expresses firefly luciferase as internal control. Plasmids were then co-transfected into HEK293 cells with different combinations of miRNA mimics and luciferase activity was evaluated in cell lysates 48 h later. The fold change of *Renilla*/firefly luciferase signal was normalized to a control group containing either a non-targeting siRNA or a miRNA

mimic without a predicted binding site in the 3' UTR fragment of the target gene.

The first gene we investigated, *Neurod1*, is an important transcription factor regulating neuronal differentiation and migration in the developing cerebral cortex⁴². *Neurod1* contains binding sites for miR-137-3p and miR-

<https://doi.org/10.1038/s42003-024-07092-7>

Article

153-3p that were previously demonstrated to co-operatively repress the gene's expression²⁰. Therefore, we used this experiment as a positive control. We independently cloned two *Neurod1* 3' UTR fragments with different lengths (274 bp and 1188 bp, respectively). The luciferase activity was significantly reduced in cells transfected with the combination of miR-137-3p and miR-153-3p compared to individual miRNAs as well as two different negative controls (siRNA and miR-128-3p), thereby confirming the co-targeting effect previously observed (Fig. 7a, b).

Src, a proto-oncogene that codes for a non-receptor protein tyrosine kinase is another important neurodevelopmental regulator that contains binding sites for both miR-137-3p and miR-153-3p in its 3'UTR. *Src* is expressed at steadily high levels in the mouse neocortex from E12.5 to P1 and overexpression of this gene leads to impaired neuronal migration due to altered adhesion properties and cytoskeletal dynamics⁴³. We observed that the combination of both miRNAs exerted a significantly stronger repressive effect on *Src* compared to each individual miRNA (Fig. 7c).

As an additional target gene for the reporter assays, we selected *Cxcl12* which is also an important regulator of early brain development. *Cxcl12* is involved in migration of NPCs, early localization of Cajal-Retzius cells in the developing cortex, and in axon guidance and pathfinding^{44,45}. *Cxcl12* is a predicted target of miR-137-3p and miR-135b-5p. Luciferase reporter assays showed that co-transfection with both miRNAs significantly increased the repressive effect compared to the negative siRNA control and treatment with each miRNA separately (Fig. 7d).

In contrast, we did not observe a significant co-targeting effect for miR-153-3p with miR-129-5p and miR-137-3p with miR-128-3p in reporter assays with *Apc* and *Ndst1*, respectively (Supplementary Fig. 5a, c). Furthermore, we aimed to investigate if higher-order co-targeting interactions, including three miRNAs would exert stronger silencing effects on gene expression. To this end, we co-transfected cells with plasmids containing the 3' UTR fragment of the *Dcx* gene and mimics of miR-128-3p, miR-129-5p, and miR-135b-5p (Supplementary Fig. 5b). In an additional assay, we cloned the 3' UTR of *Zeb2* and co-transfected cells with its targeting miRNAs – miR-129-5p, miR-137-3p and miR-153-3p (Supplementary Fig. 5d). Treatment with different miRNA mimics significantly reduced luciferase activity compared to the siRNA control in the *Zeb2* assays. However, we did not observe a significant cooperative repressive effect for either *Dcx* or *Zeb2*.

To confirm that the cooperative silencing effect for *Neurod1*, *Src*, and *Cxcl12* was mediated via direct binding of the miRNAs, we employed in vitro site-directed mutagenesis to introduce mutations in the miRNA binding sites of the 3' UTRs. We generated plasmids carrying a mutation in one of the binding sites or in both binding sites of the respective co-targeting pair. For all three genes, we observed the highest luciferase activity in the cell lysates where both miRNA binding sites were mutated. Conversely, the strongest repressive effect was detected when both binding sites were intact, thereby confirming that miRNAs acted co-operatively to exert stronger gene silencing (Fig. 7e–h). Furthermore, we investigated the expression patterns of these three genes by employing the data from Weyn-Vanhenhenryck et al.³⁷. *Neurod1* was significantly downregulated at P0 compared to E14.5 and E16.5, correlating negatively with the expression pattern of the co-targeting pair miR-137-3p and miR-153-3p (Fig. 7i, Supplementary Fig. 6a). While *Src* was not differentially regulated, it still had its expression minimum at P0 (Fig. 7j, Supplementary Fig. 6b). Interestingly, *Cxcl12* had a significantly reduced expression only at E16.5 compared to E14.5, but this pattern negatively correlated with the expression peak of miR-135b-5p at E17 (Fig. 7k, Supplementary Fig. 6c). These matching in vivo expression patterns of the miRNAs and the genes they co-target lend further support to the biological relevance of the co-operative miRNA gene silencing we observed in the luciferase assays.

Discussion

Our study provides a detailed map of the longitudinal changes in miRNA expression patterns that occur in the transition between NPCs and neurons as well as in vivo at key stages of embryonic cortical development in the

mouse. While previous studies have already employed high-throughput sequencing to examine miRNA composition in the embryonic cortex, they have focused on a single time point only^{29,46}. In contrast, in situ hybridization-based technologies have successfully profiled miRNA expression in different embryonic brain structures and at multiple time points⁴⁷, however, this analysis has been limited to a pre-selected set of miRNAs. To our knowledge, this is the first high-throughput longitudinal investigation, therefore providing a valuable resource for elucidating the regulatory role miRNAs play during murine embryonic corticogenesis.

Remarkably, the majority of the miRNAs significantly altered their expression level already at the transition from E14 to E17. This predominantly neurogenic phase is characterized by a complex interplay of multiple processes that shape late-stage embryonic corticogenesis⁴⁸. At E14, radial glia cells in the ventricular zone have switched from symmetrical to asymmetrical divisions to give rise to the basal progenitors that later generate neurons. Subsequently, newly born neurons migrate out of the ventricular zone to the upper layers of the neocortex where they differentiate into mature neurons. Upon neurogenesis completion at around E17, neural stem cells give rise to the other brain cell types including astrocytes and oligodendrocytes^{28,30}. Cell fate commitment and neuronal identity are determined by specialized transcriptional programs that occur in sequential waves and eventually result in the immense cell type diversity observed in the brain^{49,50}. The dynamic changes of miRNA expression we detected indicate that miRNA networks can act as quick regulators of these transcriptional programs by controlling the expression of cell-type specific genes⁵¹. miRNA-mediated transcriptional inhibition could also contribute to reducing excess levels of target mRNA arising as noise from transcriptional bursts and thereby ensuring appropriate cell-type or developmental-stage specific expression.

By employing a co-expression network analysis, we detected sets of co-regulated miRNAs with individual miRNAs acting as hubs at early (e.g., miR-92a/b) and late (e.g., miR-124 and miR-137) stages of neurogenesis. miR-92 is a part of the miR-17-92 cluster that is involved in the maintenance of neural stem cells, and its genetic ablation results in a reduced pool of neural stem and radial glia cells and a premature transition to intermediate progenitors⁵². Furthermore, miR-137 has been reported previously to influence neuronal differentiation via a regulatory loop between TLX and miR-137' downstream target LSD1⁵³.

Interestingly, we observed an enrichment of downregulated genes at P0 compared to E14, which were validated targets of hub miRNAs in the green module (Fig. 4e). This module consisted of miRNAs that were upregulated at P0. A GO annotation analysis revealed that many of these genes are regulators of key processes that are responsible for keeping neural stem cells in a proliferative state and blocking neuronal differentiation. For instance, the canonical NPC marker *Sox2* is crucial for the maintenance and self-renewal of progenitors^{54,55}, and silencing its expression promotes neuronal differentiation⁵⁴. Another member of the SOX transcription factor family—*Sox9*, also plays an important role in maintaining neural stem cells in the early embryonic neocortex and its expression levels determine self-renewal and neurogenic division behavior of radial glial cells⁵⁶. In fact, a recent review highlighted a complex regulatory interplay between SOX transcription factors and miRNAs that guide distinct cellular activities in the developing and adult brain under physiological and pathological conditions⁵⁷.

Green module hub miRNA targets that were downregulated at P0 also included positive regulators of Notch signaling and negative regulators of the Wnt pathway. Activation of the Notch pathway indeed leads to maintaining the neural progenitor pool⁵⁸. Furthermore, inhibiting Wnt signaling during mid and late stages of neurogenesis in the neocortex was previously reported to result in reduced neuronal production⁵⁹.

Another crucial mechanism through which miRNAs can influence the development of the cerebral cortex is via the regulation of RNA-binding proteins. In line with this, we observed that several effectors of alternative splicing whose expression significantly changed during embryonic corticogenesis were validated targets of hub miRNAs (Fig. 4f). Alternative splicing plays a pivotal role in neuronal differentiation⁶⁰, axonogenesis⁶¹ and

<https://doi.org/10.1038/s42003-024-07092-7>

Article

synapse formation⁶². In this context, miR-124 represents one of the most well-studied examples in neuronal differentiation. miR-124 targets PTBP1, a protein that represses neuronal splice patterns. The upregulation of miR-124 in neurons is sufficient to suppress the expression of *Ptbp1* and thereby induce the necessary splicing changes for the transition from NPCs to neurons³⁹. Thus, miRNAs could act as a post-transcriptional mechanism ensuring the precise spatio-temporal expression of RNA-binding proteins which is critical for proper development of the central nervous system⁶³.

Surprisingly, the gene silencing effect of most miRNAs is modest despite their crucial regulatory potential⁶⁴, indicating that—with the exception of hub miRNAs—they might be fine tuners rather than master regulators of embryonic brain development. However, the redundancy of multiple co-expressed miRNAs sharing the same target genes supports the mechanism of co-operative binding to enhance the gene-silencing effect of individual miRNAs²⁰. Accordingly, we confirmed the co-targeting for several neurodevelopmentally relevant genes in luciferase assays (Fig. 7). Furthermore, the negative correlation between the in vivo miRNA and target expression peaks strongly suggests that co-targeting is a biological phenomenon that can occur during embryonic cortical development. As 3' UTRs of mRNAs expressed in the brain are longer compared to other tissues⁶⁵ and this length even increases in neuronal transcripts⁶⁶, the brain indeed offers extremely favorable conditions for the emergence of miRNA multi-targeting networks²⁰.

Notably, significant co-targeting relationships between co-expressed miRNAs were as likely as co-targeting associations between miRNAs regulated in opposite directions. Apart from simultaneous cooperative binding to enhance gene silencing, this observation points to an alternative evolutionary need for the presence of multiple binding sites for distinct miRNAs in the same gene, namely regulating the expression at different time points or in diverse cell types. Accordingly, Nowakowski and colleagues recently reported cell-type specific miRNA-mRNA interactions in the developing human cortex using a single-cell qPCR profiling strategy⁵¹. Thus, distinct miRNAs might be responsible for silencing temporally or spatially abnormal expression of an overlapping set of genes. This explains our observation of miRNAs with opposite expression patterns that share more targets than expected by chance.

In summary, we detected dynamic changes in miRNA expression during embryonic brain development with distinct miRNAs acting as hubs in co-expression and co-targeting networks. Furthermore, we showed that miRNAs might be particularly important for controlling cell fate commitment and neuronal differentiation by silencing the expression of genes that promote neural stem cell proliferation and maintenance as well as NPC-like splicing patterns. Our study also provides additional evidence that simultaneous binding to common targets increases the transcriptional repression effect of miRNAs. To further resolve the complexity of mRNA-miRNA as well as miRNA co-targeting networks in distinct cell types in vivo, future studies should focus on single-cell high-throughput profiling techniques.

Methods

miRNA sequencing of the developing mouse cerebral cortex and in NPCs/neurons

For bulk RNA sequencing of cerebral cortex samples as E14, E17 and P0, the two cortical hemispheres of each embryo were dissected from the brains, the meninges were removed, and the cortices were stored in RNAlater solution (Sigma). To isolate total RNA (including miRNAs) from the embryonic cortices, the Trizol/Chloroform method was used. For NPC/neuron culture, the cortices of E14.5 NMRI embryos (Janvier Labs; Le Genest-Saint-Isle, France) were dissected and collected in cooled DMEM high glucose media (Gibco Life Technologies) and processed into single cells by trypsin digestion. For NPC and neuron culture, 0.2×10^6 cells per well and 1.4×10^6 cells per well, respectively, were seeded on Poly-L-ornithin and Laminin coated 6 well plates. The NPCs were cultured in neurobasal medium containing 2% B27-VitA supplement (Gibco Life Technologies), 500 μ M Glutamax (Gibco Life Technologies) and EGF (10 ng/ml) and FGF (10 ng/ml). For neural

differentiation, the cells were cultured in neurobasal medium containing 2% B27 supplement (Gibco Life Technologies) and 500 μ M Glutamax (Gibco Life Technologies). Total RNA, including miRNA, was isolated from the NPCs and neurons as well as from cortices of female and male NMRI embryos (Janvier Labs; Le Genest-Saint-Isle, France) at the time points E14, E17 and P0 ($n=6$ embryos per sex and time point) using the Qiagen miRNeasy mini kit (CatNo. 217004; Qiagen; Hilden, Germany). To determine the concentration of the isolated RNA a NanodropOne Spectrometer was used (ThermoScientific). 500 ng of total RNA, including miRNA, were used as an input for library preparation with the Bioo Scientific NextFlex small RNA v3 Seq Kit (CatNo. NOVA-5132-05; Bioo Scientific; Austin, USA). Library preparation was conducted according to the kit manual. Size distribution and concentrations of the prepared libraries were checked by Qubit dsDNA High Sensitivity Assay (CatNo. Q32851; Thermo Scientific; Waltham, USA). 0.5 nanomoles (NPCs/neurons) or 4 nanomoles (cerebral cortex samples) of the prepared miRNA libraries were loaded on a High Output v2 kit (75 cycles) Illumina cartridge which was run on a NextSeq 500 device.

miRNA sequencing data pre-processing

After the sequencing, bcl2fastq v2.17.1.14 conversion software (Illumina, Inc.) was used to demultiplex sequencing data and convert base call (BCL) files into fastq files. The trimming of the fastq files was conducted in two steps as suggested by the NEXTflex™ Small RNA Trimming Instructions. Briefly, sequencing adapters (TGGAATTCTCGGGTCCAAGG) were trimmed and reads shorter than 15 nucleotides were removed from further analysis. Afterwards, 4 bases from either side of each read were trimmed using Cutadapt v1.18. Quality control checks were performed on the trimmed data with FastQC v0.11.7.

miRNA differential expression analysis

miRNA samples with at least 20 million reads were further analyzed, thus 2 female samples at E14 not meeting this criteria were excluded. Using miRDeep's v2.0.1.2 *mapper.pl* script, miRNA reads were mapped to the *Mus musculus* GRCm38 genome. Afterwards, known and novel miRNA were identified using the *miRDeep2.pl* script. Prior to differential expression analysis, miRNAs with CPM expression values less than 10 were filtered out using edgeR v3.30.3. Differential expression analysis was then performed with DESeq2 v1.28.1. miRNAs with an adjusted p -value < 0.05 and an absolute log fold change exceeding 0.5 were considered differentially expressed. P -values were corrected for multiple comparisons with the Benjamini-Hochberg method.

Weighted gene co-expression network analysis

We performed a Weighted Correlation Network Analysis (WGCNA)³⁶ to find clusters or "modules" of co-expressed miRNAs. For the analysis, a *bicor* correlation type and a *signed* network type with soft-thresholding power of 24, minimal module size of 5 and dynamic tree cut height of 0.2 were applied. Target prediction of the miRNAs in each module was performed using the TargetScanMouse database v7.2⁶⁷. Functional enrichment analysis of the different modules in the co-expression network was conducted using the clusterProfiler v4.6.2 R package and the target genes of the miRNAs in the respective module as input.

Key driver analysis

To identify hub (or key driver) miRNAs in the modules of the co-expression network, we performed a key driver analysis as previously described^{134,35}. First, we used the algorithm for the reconstruction of cellular networks (ARACNE)⁶⁸ as implemented in the bnlearn R package v4.8.3 to obtain an undirected gene regulatory network from the expression levels of the miRNAs in the respective WGCNA module. Next, we performed key driver analysis on the ARACNE reconstructed network using the KDA R package v0.2.2 (<https://github.com/mw201608/mnml-public/tree/master/pkgs>) to identify important regulatory miRNAs.

<https://doi.org/10.1038/s42003-024-07092-7>

Article

Analysis of publicly available bulk RNA-seq data of the developing mouse cortex

To explore the expression of target genes during cortical development, we re-analyzed publicly available data from the study by Weyn-Vanhenhenryck et al.³⁷ containing RNA-seq of the mouse cortex. We focused on E14.5, E16.5, P0 as these were comparable with the time points in our study. Fastq files were downloaded from the NCBI Short Read Archive, accession number SRP055008. After trimming with BBDuk v39.01, reads were mapped to the Gencode mm39 reference genome (released 19.10.2022) using STAR v2.7.10b. A count matrix was obtained using FeatureCounts provided by SubRead v2.0.6. Differential expression analysis was performed with DESeq2 v1.40.1 with default settings. Genes with an adjusted *p*-value (Benjamini–Hochberg method) <0.05 were considered to be differentially expressed.

miRNA expression profiling using RT-qPCR

miRNA expression patterns identified by small RNA sequencing were validated with the TaqMan MicroRNA Assay (Applied Biosystems). Reverse transcription was performed using the TaqMan MicroRNA Reverse Transcription Kit (Applied Biosystems; CatNo. 4366596). RT-qPCRs were conducted with the TaqMan Universal Master Mix II, no UNG (Applied Biosystems; CatNo. 4440040) on a StepOnePlus Real-Time PCR System (Applied Biosystems). The U6 snRNA was used as a control for normalization of experimental samples. Relative quantification (RQ) values of miRNA expression were calculated with the $\Delta\Delta CT$ method. Expression levels in NPCs and E14 samples, respectively, were used as reference groups. Primers used for the RT-qPCR analysis are shown in Supplementary Table 1.

miRNA co-targeting prediction

miRNA co-targeting analysis was performed using a custom R script. We employed the TargetScanMouse database v7.2 to identify the broadly conserved mRNA targets for each miRNA. miRNAs which belong to the same broadly conserved family and therefore have identical gene target sets were grouped together for further analysis. Additionally, we only kept miRNAs with at least 300 targets²⁰.

Subsequently, we created a custom control set for each miRNA, containing genes with similar 3' UTR length, GC content, and sequence conservation as the actual genes included in the respective target set based on a case-control strategy. To select the best matching control for a gene *X* from the respective target set (case), first we filtered the potential pool of candidates for genes with a 3' UTR length within the range of 0.85–1.15 of the 3'UTR length of target gene *X*. Then, we filtered out genes with a GC content outside the range of 0.95–1.05 of the GC content of gene *X*. Finally, we eliminated candidates with a phyloP score outside the range of 0.8–1.2 for gene *X*. If more than one candidate remained after the filtering steps, a control gene *Y* for the target gene *X* was picked randomly. If the filtering steps returned an empty set, no control gene was selected for the respective target. This procedure was repeated for all genes included in the target set for the miRNA. The filtering cut-off values were selected empirically to maximize the number of controls while simultaneously minimizing the difference in the 3' UTR length, GC content, and phyloP score distributions of genes in the target and control sets. The similarity of the distributions of the three parameters between the control and target sets was ensured by non-significant pairwise Wilcoxon tests.

We considered miRNA *A* and miRNA *B* to be a co-targeting pair if the intersection of their target sets contained more genes than what would be expected by chance. To this end, we compared the observed number of common targets with the expected number obtained by intersecting the target set of miRNA *A* with the control set of miRNA *B* and vice versa. This yields two comparisons for each pair of miRNAs whose significance was evaluated with a Fisher's exact test. If both tests were statistically significant after a false discovery rate *p*-value adjustment (Benjamini–Hochberg method), then we considered miRNA *A* and miRNA *B* to be a bidirectional co-targeting pair. To quantify the magnitude of the co-targeting relationship, we calculated the odds ratios with values significantly higher than 1

Table 1 | Contingency table used to calculate the association between intra- and inter-modular miRNA co-targeting relationships for the black and green WGCNA modules

	Significant co-targeting relationship	Non-significant co-targeting relationship
Intra-modular	<i>m</i>	<i>M</i> – <i>m</i>
Inter-modular	<i>n</i>	<i>N</i> – <i>n</i>

m represents the number of significant intra-modular co-targeting relationships, *M* corresponds to the total number of possible intra-modular relationships, *n* corresponds to the number of significant inter-modular relationships and *N* refers to the total number of possible inter-modular relationships.

We used the following formula to calculate *M*:

$$M = x(x - 1)/2$$

where *x* corresponds to the number of miRNAs in the respective module. The total number of possible inter-modular relationships was estimated with the formula:

$$N = xy$$

with *x* being the number of miRNAs in the module of interest and *y* corresponding to the number of miRNAs in the remaining modules.

corresponding to a pair of miRNAs sharing a significantly higher number of targets than what would be expected by chance. Higher odds ratios indicate a higher number of shared targets. To ensure that co-targeting pairs do not originate from identical seed sequences, miRNAs having identical seeds up to one mismatch were excluded a priori from the statistical analysis.

Comparing the number of intra- and inter-modular co-targeting relationships

To investigate if the black or green WGCNA modules contain more intra-modular (miRNAs of the same module) than inter-modular (miRNAs from different modules) co-targeting relationships, we performed a Fisher's exact test on the contingency table shown in Table 1.

Luciferase reporter assays

3' UTR fragments of miRNA target genes (for primer sequences see Supplementary Table 2) were cloned into the XhoI/NotI sites downstream of the synthetic *Renilla* luciferase gene of the psiCHECK-2 vector (Promega; CatNo. C8021). Mutations in the miRNA binding sites were introduced using the QuikChange II XL system (Agilent Technologies; CatNo. 200521-5). Primers used are shown in Supplementary Table 2. 5×10^4 HEK293 cells were seeded into each well of a 12-well plate. 24 h later, 200 ng psiCHECK-2 reporter plasmid were co-transfected with 5 μ l miScript miRNA mimics (Qiagen; CatNo. 219600) using 4 μ l Lipofectamine 2000 Transfection Reagent (Thermo Fisher Scientific; CatNo. 11668019). Luciferase reporter assays were conducted 48 h later using the Dual-Luciferase Reporter Assay System (Promega; CatNo. E1980). Luciferase activity was measured on a CentroXS LB 960 (Berthold Technologies).

Statistics and Reproducibility

In the analysis of qPCR and luciferase reporter assay data, two groups were compared statistically using an unpaired *t*-test or Welch's *t*-test in case of unequal variance between groups. For comparisons of three groups, a one- or two-way analysis of variance (ANOVA) followed by Tukey's post hoc test was performed. The assumptions of the linear model were evaluated by inspecting Q-Q plots and fitted values vs. residuals plots. Relative quantification values from the RT-qPCR assays were log_e-transformed prior to statistical testing. All *p*-values are two-tailed and a *p*-value ≤ 0.05 was considered statistically significant. Statistical analysis was performed using R v. 4.2.2.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

The raw RNA-seq data were uploaded to the Sequence Read Archive (SRA) data base under the accession number PRJNA1018560. Individual values underlying figures are provided in Supplementary data 5.

Ethics

We have complied with all relevant ethical regulations for animal use. Ethical review and approval were not required for the animal study because the study did not include any animal experiments requiring approval. To carry out this study, mice were killed for organ removal. In Germany, this procedure is notifiable but does not require approval by an ethics committee.

Additional information

Supplementary information The online version contains supplementary material available at <https://doi.org/10.1038/s42003-024-07092-7>.

Stage-specific expression patterns and co-targeting relationships among miRNAs in the developing mouse cerebral cortex

Hristo Todorov, Stephan Weißbach, Laura Schlichholz, Hanna Mueller, Dewi Hartwich, Susanne Gerber, Jennifer Winter

Supplementary Figure 1. Top 20 most highly expressed miRNAs in E14, E17 and P0 mouse cortical samples. Values in the heatmap correspond to log₂-transformed normalized counts. M – males, F – females.

Supplementary Figure 2. Differential expression analysis of miRNAs in neuronal progenitor cells (NPCs) vs. neurons. **a** Volcano plot of differentially expressed miRNAs. Orange dots correspond to miRNAs up-regulated in NPCs, blue dots signify miRNAs that are up-regulated in neurons. Non-significant results are shown in gray, $n = 3$ biological replicates per group. **a-c** Venn diagrams showing the overlap of miRNAs that were up- or down-regulated in bulk cortical samples from E14 vs. P0 and NPCs vs. neurons. **d** Heatmap showing the expression levels of the top 20 down- and top 20 up-regulated miRNAs in NPCs vs. neurons. Values correspond to z-scores of normalized miRNA expression.

Supplementary Figure 3. Weighted gene co-expression network analysis. Histograms show the frequency distribution for the number of miRNAs targeting a gene for the black (**a**) and green (**b**) modules. **c** Venn diagram with the overlap of common genes targeted by miRNAs in the black and green modules. Target predictions were obtained from TargetScan using conserved miRNA families and binding sites. **d** Venn diagram with validated targets for conserved hub miRNAs from the black and green module obtained from miRTarBase. **e-h** Box

plots with the module membership and gene-trait significance values for the hub miRNAs and the remaining miRNAs in the black and green modules. *** $p < 0.001$, * $p < 0.05$, unpaired t-test.

Supplementary Figure 4. Relative quantification of miRNA expression using RT-qPCR. **a-e** Expression levels of miRNAs selected for luciferase experiments in neuronal progenitor cells (NPCs) versus neurons. Relative quantification (RQ) values were normalized to the mean expression in NPCs. **f-j** Expression levels in cortical samples at E14, E17 and P0. RQ values were normalized to the mean expression in the E14 group. Data are shown as mean \pm standard error of the mean and individual values, $n=3$ biological replicates per group. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, unpaired t-test of log-transformed RQ values.

Supplementary Figure 5. Luciferase activity in lysates of HEK293 cells transfected with plasmids containing 3' UTR fragments of target genes. Lysates were co-transfected with different combinations of miRNA mimics. Fold change (FC) of luciferase activity was obtained by calculating the ratio of *Renilla* luciferase and firefly luciferase activity and then normalizing to the mean of the control siRNA or miRNA group. Locations of the binding sites in the 3' UTR of the respective gene are represented by colored dots. The length of the 3' UTRs is indicated in kbp. Data are shown as mean \pm standard error of the mean and individual values, n=9

replicates per group. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, only statistical comparisons containing groups with at least two miRNA mimics are shown, # $p < 0.05$ siRNA control vs. all other groups, two-way analysis of variance followed by Tukey's post-hoc test.

Supplementary Figure 6. Expression of target genes from the luciferase assay at different developmental time points. Bar plots show DESeq2-normalized counts for target genes that were used in the luciferase experiments at E14.5, E16.5 and P0 of cortical development. Data are depicted as mean and individual values. ** $p < 0.01$, *** $p < 0.001$, **** $p < 0.0001$, Wald test from DESeq2, $n = 2$ biological replicates per group. The expression values of genes were obtained by reprocessing data from the bulk RNA-seq study of the developing cerebral cortex by Weyn-Vanhentenryck et al. ¹

Abstract

Background: Gene expression and alternative splicing are strictly regulated processes that shape brain development and determine the cellular identity of differentiated neural cell populations. Despite the availability of multiple valuable datasets, many functional implications, especially those related to alternative splicing, remain poorly understood. Moreover, neuroscientists working primarily experimentally often lack the bioinformatics expertise required to process alternative splicing data and produce meaningful and interpretable results. Notably, re-analyzing publicly available datasets and integrating them with in-house data can provide substantial novel insights. However, such analyses necessitate developing harmonized data handling and processing pipelines which in turn require considerable computational resources and in-depth bioinformatics expertise.

Results: Here, we present Cortexa—a comprehensive web portal that incorporates RNA-sequencing datasets from the mouse cerebral cortex (longitudinal or cell-specific) and the hippocampus. Cortexa facilitates understandable visualization of the expression and alternative splicing patterns of individual genes. Our platform provides SplicePCA—a tool that allows users to integrate their alternative splicing dataset and compare it to cell-specific or developmental neocortical splicing patterns. All standardized gene expression and alternative splicing datasets can be downloaded for further in-depth downstream analysis without the need for extensive preprocessing.

Conclusions: Cortexa provides a robust and readily available resource for unraveling the complexity of gene expression and alternative splicing regulatory processes in the mouse brain. The data portal is available at <https://cortexa-rna.com/>

Keywords: Alternative splicing, Gene expression, Cerebral cortex, Hippocampus, Embryonic brain development

Background

Transcriptional regulation plays a crucial role in the developing and adult mammalian brain [1–3]. Major changes during development can be observed particularly in gene expression [4, 5] and alternative splicing [6–9] patterns.

Gene expression is the best-understood, and most extensively studied among these processes. It has been a major focus in the study of brain development [10], cell identity [11, 12], and disease-related alterations [13–15]. However, a common issue with gene expression analysis when comparing results from heterogenous sources is the occurrence of batch effects that are unrelated to biological factors, due to differences in sequencing technology, experimental handling, and bioinformatic processing [16–20].

Alternative splicing (AS) of precursor mRNA is a fundamental process that enables the generation of various transcripts and subsequent proteins from the same gene. Therefore, it significantly increases the available transcriptomic variability [21]. AS is particularly important in the central nervous system, playing a vital role during cortical development [6, 21] and in the determination and maintenance of neuronal cell identity [22]. Moreover, AS is an important regulator of gene expression since it can initiate the degradation of mRNA by introducing premature stop codons which leads to nonsense-mediated decay [23].

Although several high-quality datasets focusing on AS in the murine brain are freely available, interpreting the different types of splicing events for individual genes remains challenging. Moreover, harnessing the potential of multiple datasets requires a harmonized processing strategy to ensure the comparability of results. A limitation of existing data portals, namely, the single cell atlas of the Allen Brain Institute [24], Neuron Subtype Transcriptome [25], or Brain RNA-Seq [26], is that they are focused on gene expression and do not offer the analysis of custom data in the context of cell-specific or developmental changes in alternative splicing.

Here, we introduce Cortexa—a novel data portal for accessing a variety of high-quality neocortical and hippocampal transcriptomic datasets, analyzed for gene expression and alternative splicing. Batch effects between different studies have been minimized using a standardized analysis pipeline (Figure 1a). We offer easily interpretable summaries and visualization of results that allow a broad range of scientists to explore the expression and AS patterns of individual genes. Additionally, we developed SplicePCA—a tool that performs a principal component analysis of splicing events for a selected gene set and enables the investigation of splicing patterns related to developmental changes or variations across cell types [6, 27–29]. All standardized datasets included in Cortexa are publicly available for download, allowing users to integrate them into their research easily.

Construction and content

Datasets

We analyzed publicly available *in vivo* paired-end RNA sequencing data of the mouse cerebral cortex and hippocampus as well as *in vivo* data from neural progenitor cells (NPCs) and neurons (Fig. 1c) with a minimum read length of 100 bp. We downloaded the sequencing data from NCBI SRA or GEO respectively. Specifically, we used SRP055008 [6], GSE133291 [22], and GSE96950 [9]. Further datasets can easily be integrated, refer to <https://cortexa-rna.com/datasets>.

RNA-seq analysis

We used a standardized RNA-seq pipeline (Fig. 1a) to analyze the transcriptomic data for gene expression and alternative splicing. In brief, we trimmed the reads for

Fig. 1 **a** Standardized RNA-seq pipeline used for gene expression (blue) and alternative splicing (orange). **b** Visualization of possible alternative splicing events and the splicing outcome referred to as spliced-in and spliced-out. **c** Publicly available datasets integrated into Cortexa: SRP055008 [6], GSE133291 [22], and GSE96950 [9]

adapter sequences with BBDuk (version 39.01) [30]. The trimmed reads were aligned to the reference genome mm39 (released 19.10.2022) downloaded from Gencode using STAR (version 2.7.10b) [31] and indexed using samtools (version 1.18) [32]. FeatureCounts, provided by SubRead (version 2.0.6) [33], was used to quantify the expression of each respective gene. All gene expression counts were normalized to transcripts per million (TPM).

We utilized rMATs turbo (version 4.1.2) [34] with default settings to detect AS events. We analyzed the data for five alternative splicing events: cassette exon (skipping exon), mutually exclusive exons, intron retention, alternative A5' splice site, and alternative A3' splice site (Fig. 1b), as defined in rMATs [34]. The coverage for sashimi plots was analyzed in 10 bp steps with bamCoverage (version 3.5.2) from deepTools2 [35] converted to wig with Encode bigWigToWig.

Webapp

The web application was built with Next.js frontend framework, utilizing SQLite database for backend data storage. TypeScript enhances code maintainability and type safety, while Tailwind CSS streamlined styling. Prisma serves as the ORM tool for efficient database management. The application follows the REST principles for communication between frontend and backend components, optimizing interoperability and scalability. The website is hosted on servers of the Johannes Gutenberg University, Mainz, Germany. A detailed tutorial on how to interpret alternative splicing events presented in Cortexa is provided at <https://cortexa-rna.com/tutorial>.

Visualization of genes

Gene expression was normalized to transcripts per million (TPM) and represented as a barplot for each dataset. Alternative splicing events (Fig. 1b) are visualized as sashimi plots.

SplicePCA

SplicePCA performs principal component analysis (PCA) on averaged percentage spliced-in (PSI) values (Fig. 2a). Initially, the user can either select a subset of genes or perform SplicePCA on all genes. All events that have missing values are removed from the subsequent analysis. Next, PSI values are averaged within their respective group (e.g. E14.5 from the developmental data set [6]). These averaged PSI values are the input for the PCA, and the resulting values are plotted and available for download. Moreover, SplicePCA allows users to integrate their in-house analyzed output files (rMATS). We recommend processing the files as described in Sect. 3.2 and in the tutorial available at https://github.com/s-weissbach/cortexa_SplicePCA_example/.

Example usage of SplicePCA

To demonstrate the use of SplicePCA, we obtained *Nova2*- knock-out (KO) and wild-type (WT) data from NCBI GEO with the accession number GSE103314 [36]. We performed quality control, trimming, alignment, and alternative splicing analysis as described in Sect. 3.2 RNA-seq analysis.

Subsequently, the cassette exons from the rMATS output file were uploaded to <https://cortexa-rna.com/pca> and analyzed in the context of developmental [6] and NPC/neuron-specific [9] alternative splicing events. Next, the results from SplicePCA were downloaded and plotted using matplotlib (version 3.9.0) [37].

Utility and discussion

Alternative splicing is a prevalent regulatory mechanism in the brain that plays an important role during development and in specifying and maintaining neural cell types [6, 7, 9, 22, 28, 36, 38]. However, *Mus musculus* has ~22,000 protein-coding genes [39] of which almost all multi-exon genes undergo alternative splicing [40]. Functional implications of these alternative splicing events remain in many cases elusive. Cortexa is an easy-to-use web tool to access alternative splicing events for genes of interest in a developmental and neuronal cell-type-specific context to formulate and investigate research hypotheses.

Additionally, principal component analysis has proven to be a powerful tool to summarize alterations in the alternative splicing landscape [6, 27–29]. Representation of samples in two-dimensional space allows investigating the similarity or divergence of global splicing patterns between different experimental conditions. In our analysis of developmental alternative splicing, we observed a characteristic bell-shaped trajectory across diverse iterations, which aligns with findings reported in the literature [6]. However, the interpretation of principal components can be challenging in terms of associating them with biologically meaningful factors. By design, principal components capture the direction of maximal variance in the original data [41] which

Fig. 2 **a** Schematic representation of SplicePCA. SplicePCA takes percentage spliced-in (PSI) values for all genes or a selected subset of genes as input. Alternative splicing events with missing values are removed from the dataset. The remaining PSI values are averaged over individual replicates per experimental group. Finally, PCA is performed on the averaged data, resulting in a representation of splicing patterns across groups in two-dimensional space. **b** Cassette exon data of cortical samples of WT (E18.5) and Nova2-KO (E18.5), analyzed with SplicePCA and compared to splicing changes across normal development of the mouse cortex. PCA of alternative splicing data across cortical development forms a characteristic bell-shaped trajectory (indicated by gray arrows) with P0 as its inflection point. The conditional knock-out of Nova2 resulted in a substantial deviation from the inferred normal splicing trajectory. Nova2-KO samples (E18.5) were associated with a less mature splicing pattern than E16.5 wild-type samples

does not necessarily reflect experimental or biological factors. Despite these limitations, PCA remains a valuable exploratory tool, and SplicePCA offers a user-friendly method for investigating alternative splicing in the context of development or different cell types.

Using SplicePCA, researchers can select splice events for specific genes, integrate their data, and interpret results in the context of cortical development and specific neuronal cell types. To showcase the usefulness of this approach, we re-analyzed cortical *Nova2*-KO and WT samples at embryonic day E18.5 [36] and used the SplicePCA tool. NOVA2 belongs to the class of RNA-binding proteins, governing alternative splicing during cortical development and in mature neurons [42]. Specifically, NOVA2 is required to regulate neuronal migration through splicing *Dab1* which is part of the Reelin pathway [2]. By using SplicePCA, we revealed a striking effect of *Nova2*-KO during cortical development. E18.5 knockout samples were located between E14.5 and E16.5 wild-type samples on the inferred developmental splicing trajectory, indicating a less mature splicing pattern (Fig. 2b). Thus, NOVA2 splicing activity contributes significantly to the splicing changes between E14.5 to E18.5, as reported previously [2, 36, 43]. These results support the relevance of SplicePCA which combines available datasets with new datasets. Cortexa thus allows the use of publicly available data without extensive re-analysis, which would otherwise require significant computational resources.

Conclusions

In summary, Cortexa gives access to high-quality, publicly available transcriptomic data to a broad range of scientists without the need to gain expertise in the computational aspects of gene expression and alternative splicing analysis. For experienced users, SplicePCA offers a powerful tool to summarize alterations in the alternative splicing landscapes upon experimental manipulation and compare results to the normal splicing trajectory during cerebral cortical development or in distinct neuronal cell types. Ultimately, Cortexa offers an easy-to-use extensive platform for gaining novel insights into gene expression and alternative splicing regulatory processes of the mouse brain.

ABSTRACT

Voltage-gated calcium channels (VGCCs) represent key regulators of the calcium influx through the plasma membrane of excitable cells, like neurons. Activated by the depolarization of the membrane, the opening of VGCCs induces very transient and local changes in the intracellular calcium concentration, known as calcium nanodomains, that in turn trigger calcium-dependent signaling cascades and the release of chemical neurotransmitters. Based on their central importance as concierges of excitation-secretion coupling and therefore neuronal communication, VGCCs have been studied in multiple aspects of neuronal function and malfunction. However, studies on molecular interaction partners and recent progress in omics technologies have extended the actual concept of these molecules. With this review, we want to illustrate some new perspectives of VGCCs reaching beyond their function as calcium-permeable pores in the plasma membrane. Therefore, we will discuss the relevance of VGCCs as voltage sensors in functional complexes with ryanodine receptors, channel-independent actions of auxiliary VGCC subunits, and provide an insight into how VGCCs even directly participate in gene regulation. Furthermore, we will illustrate how structural changes in the intracellular C-terminus of VGCCs generated by alternative splicing events might not only affect the biophysical channel characteristics but rather determine their molecular environment and downstream signaling pathways.

Ion channels; voltage-gated calcium channels; VGCC auxiliary subunits; $\alpha_2\delta$ subunits; $\text{Ca}_v\beta$ subunits; synaptogenesis; gene regulation; synaptic transmission; voltage-induced calcium release; alternative splicing

Introduction

Transient changes of the intracellular calcium concentration are a major trigger for many signaling cascades and cellular processes. Besides being a key parameter for neuronal communication, intracellular calcium levels control the entire cell life from fertilization to programmed cell death and regulate, inter alia, gene expression, heart and muscle contraction, as well as enzyme activity within subcellular compartments [1–3]. In excitable cells like neurons, voltage-gated calcium channels (VGCCs) are important regulators of the calcium concentration by controlling the influx of calcium ions (Ca^{2+}) across the plasma membrane [4–6]. The huge signaling power of Ca^{2+} , which is the most widely used and at the same time most strictly controlled second messenger molecule [1,7], might account for the fact that mutations in VGCCs have been reported in the

context of severe disorders reaching from cardiovascular channelopathies to neurological and psychiatric conditions such as ataxic and epileptic phenotypes, chronic pain, autism, schizophrenia, and depression [8–10]. However, there is a growing body of evidence suggesting that the functional relevance of VGCCs goes beyond their central role as Ca^{2+} -conducting elements. One structural feature that might facilitate such a many-sided picture of VGCCs is their design as multi-subunit complexes. The basic Ca^{2+} -conducting pore is formed by the α_1 subunit, a 190–270 kDa membrane-spanning protein. Today, ten variants of the pore forming α_1 calcium channel subunits have been described and grouped into three families, termed Ca_v1 , Ca_v2 and Ca_v3 , based on their biophysical kinetics and pharmacological properties [4,11]. This diversity of calcium channel phenotypes is strongly increased by the association of

the auxiliary subunits β , $\alpha_2\delta$, and γ as well as many other regulatory proteins that interact with specific binding domains located in the intracellular loops of α_1 [9,12]. Historically, the functional importance of auxiliary VGCC subunits was considered primarily in association with the α_1 pore of Ca_V1 and Ca_V2 high-voltage-activated (HVA) VGCCs. From this point of view, β and $\alpha_2\delta$ isoforms were extensively shown to promote the trafficking of the channel to the membrane, as well as to significantly modulate the biophysical properties of the multi-subunit channel complex [13,14]. However, several reports published over the last two decades demonstrate that VGCC auxiliary subunits can serve additional functions, which do not necessarily involve or require a direct interaction with the channel pore. Furthermore, there are studies suggesting that the pore-forming subunit of VGCCs, besides being the traditional source of Ca^{2+} from the extracellular space, has some side-functions, e. g. as voltage sensor and interaction partner for signaling complexes as well as in gene expression. These extended roles of VGCCs will be discussed in the following to illustrate some possibilities of how VGCCs might participate in neuronal network development, maintenance, and plasticity.

VGCCs: Not only voltage-gating but voltage-sensing

As already mentioned above, VGCCs are key regulators of the Ca^{2+} influx across the plasma membrane of excitable cells. In neurons, they have been widely described to shape neuronal communication by initializing the release of neurotransmitter molecules. This process mainly involves the transient influx of Ca^{2+} in response to the depolarization of the plasma membrane triggered by an arriving action potential and is therefore known as excitation-secretion coupling [4–6]. However, besides the Ca^{2+} -conducting aspect, a second key feature of VGCCs is their ability to sense membrane depolarization to initialize channel gating. The role VGCCs as voltage sensors was firstly described in skeletal muscle. Here, the excitation-contraction coupling does not require the influx of extracellular Ca^{2+} via VGCCs but rather depends on their voltage-sensing properties to trigger the release of Ca^{2+} from intracellular stores of the

sarcoplasmic reticulum [15–17]. This functional coupling involves the physical interaction of $\text{Ca}_V1.1$, a member of the Ca_V1 family, and calcium release channels in the sarcoplasmic reticulum called ryanodine receptors (RyR), especially the isoform 1, called RyR1. When binding to the skeletal RyR1, $\text{Ca}_V1.1$ transduces the sarcolemma depolarization to directly induce a mechanical gating of RyR1 by conformational interaction resulting in calcium release from intracellular stores [18,19]. Interestingly, the molecular basics and, more importantly, a similar process of voltage-induced calcium release (also called depolarization-induced calcium release) has been documented in the brain and spinal cord [20–23]. Mouton and colleagues have found RyR1 channels, although poorly expressed in the brain when compared to the other RyR isoforms 2 and 3 [23–27], in a complex with the pore-forming subunits of the Ca_V1 family members $\text{Ca}_V1.2$ and $\text{Ca}_V1.3$ in the rat brain [22]. The mechanical coupling between RyR1 and Ca_V1 channels was later shown to be specific for $\text{Ca}_V1.2$, while RyR2 was associated with $\text{Ca}_V1.3$ in spinal cord dorsal columns and whole brain [20]. A study by Kim et al. has further characterized the specific interaction of $\text{Ca}_V1.3$ and RyR2 in the rat hippocampus and demonstrated the importance of both N termini of $\text{Ca}_V1.3$ and RyR2 for their functional coupling [23]. Notably, also the activation of RyR2 in hippocampal neurons seems to be independent of the Ca^{2+} influx through $\text{Ca}_V1.3$ since RyR2 opening was also triggered in Ca^{2+} -free extracellular solution [23]. This highlights the function of $\text{Ca}_V1.3$ as a voltage sensor in neurons, which seems to differ from its classical role in the cardiac muscle where $\text{Ca}_V1.3$ opening has been widely reported to trigger calcium-induced calcium release [28]. Although the co-localization of Ca_V1 isoforms and RyRs in neurons was confirmed using immunocytochemistry and super-resolution microscopy [23,29], it has been noted that only a few of the Ca_V1 -RyR complexes appear co-localized and are sparsely distributed along axon cylinders [20]. More recently, studies have revealed additional interaction partners, including potassium channels and junctophilin proteins, participating in a multi-protein complex on the junction between the outer plasma membrane and the ER in mammalian

neurons (Fig.1) [29,30]. However, further investigation is necessary to evaluate the stability of these complexes and their functional implication for, e. g. synaptic plasticity. Suggestions have been made on a role in activity-dependent transport of signaling molecules [20], neuronal excitability [29], and a possible link to transmit membrane activity to gene expression in the nucleus [22]. From a pathophysiological perspective, it has been shown that RyR1 mediates the release of damaging quantities of Ca^{2+} from the ER when triggered by ischemic depolarizations sensed by $Ca_v1.2$ in rat dorsal columns [20]. Therefore, the voltage-sensing contribution of VGCCs in the release of Ca^{2+} from intracellular stores should be considered when studying pathophysiological elevations of calcium levels involved in, e.g. axonal damage [31]. Although a participation of the Ca^{2+} influx through VGCCs cannot be ruled out completely, especially for $Ca_v1.3$ -RyR2-complexes, this functional coupling is a first example of how VGCCs, as calcium sensors and interaction partners, can contribute to more complex signaling mechanisms.

C-terminal fragments of the VGCC pore and $Ca_v\beta$ subunits participate in gene regulation

Since intracellular Ca^{2+} acts as a second messenger molecule in a plethora of signaling pathways [1], it is evident that VGCCs, being main plasma membrane Ca^{2+} sources in excitable cells, contribute to transcriptional regulation processes [32]. This excitation-transcription coupling allows the conversion of activity-induced, very local calcium transients into long-term effects on gene regulation pathways with distinct transcription factors. Early studies have already demonstrated that the genes regulated via VGCC-induced Ca^{2+} influx differ from those targeted by other Ca^{2+} origins, for example, receptor-activated Ca^{2+} channels like NMDA receptors, store-operated Ca^{2+} channels like ORAI and TRP members, or by Ca^{2+} release from intracellular stores [33,34]. To date, many pathways orchestrating neuronal development, survival, and communication have been identified that specifically involve VGCCs' Ca^{2+} signaling to activate CREB [35,36], NFAT [37] or downstream regulator element antagonist modulator (DREAM) transcription factors [38], to name only a few [32].

Figure 1. VGCCs as voltage sensors.

As known from the skeletal muscle, also in neurons VGCCs have been shown to colocalize with ryanodine receptors (RyR) in the endoplasmic reticulum and trigger RyR-mediated Ca^{2+} release from intracellular stores. Importantly, the RyR opening, especially of RyR isoform 1, was shown to be independent of the ionic activity of the VGCCs but rather require the conformational change of the voltage-sensing transmembrane helices of the VGCC pore induced by membrane depolarization, a process called voltage-induced calcium release. Additional interaction partners like voltage-gated (Kv) or Ca^{2+} -activated (KCa) potassium channel and membrane-binding proteins, junctophilins, might complement and stabilize this functional complex.

Even if the specific contribution of VGCCs has been reported to initialize these pathways, it is the transcriptional signaling power of Ca^{2+} in combination with accessory Ca^{2+} -binding proteins that allows for the nuclear forwarding and transcriptional action described above. However, several observations have been made, underpinning the idea that VGCC subunits and intracellular domains might also directly act as gene regulators (Fig.2).

In 2006, two independent studies have reported C-terminal fragments of $\text{Ca}_V1.2$ and $\text{Ca}_V2.1$ that translocate to the nucleus of neurons in vitro and in vivo [39,40]. Gomez-Ospina et al. describe a so-called calcium channel associated transcriptional regulator (CCAT), a C-terminal fragment of the $\text{Ca}_V1.2$ channel subunit. Initially, it was assumed that CCAT is proteolytically processed from the full-length $\text{Ca}_V1.2$. However, later studies have shown that an internal promoter located in exon 46 of the *CACNA1C* gene might drive CCAT's expression independently of the $\text{Ca}_V1.2$ channel protein [41]. CCAT was verified in many different neuronal cell types throughout the brain, with a strong nuclear expression in GAD65-positive inhibitory neurons [39,41]. Notably, its nuclear localization is developmentally regulated and controlled by changes in intracellular calcium levels [39]. In the nucleus, CCAT associates with the transcriptional regulator p54(nrb)/NonO [39] and can activate transcription reporters and endogenous genes affecting, for example, cell excitability, neurite extension, and neural differentiation [42]. A similar observation has been made by Kordasiewicz and colleagues, who have found a C-terminal fragment of the neuronal $\text{Ca}_V2.1$ VGCC, which they have termed $\alpha_1\text{ACT}$, enriched in nuclei of cerebellar neurons [40]. The expression of $\alpha_1\text{ACT}$ was proven to involve the cap-independent translation as a second gene product via an internal ribosomal entry site (IRES) located in the C-terminus of the *CACNA1A* gene [43]. Using chromatin immunoprecipitation-based sequencing and high-throughput RNA sequencing (RNA-seq), $\alpha_1\text{ACT}$ was shown to orchestrate a complex network of neuronal genes associated with neurogenesis (*Dusp4*, *Efnb2*, *Fgfr3*, *Gfra2*, *Ntn1*, *Ptger3*, *Penk*, and *Odc1*), synaptic transmission (*Hcn4*, *Slc18A3*, and *Syn2*), and cell adhesion (*L1cam*) essential for early

cerebellar development and neonatal survival [43,44]. Tet-off transgenic reintroduction of $\alpha_1\text{ACT}$ in Purkinje cells of knockin-knockout compound heterozygote mice (KIKO), which exhibit a marked reduction of the full-length $\text{Ca}_V2.1$ mRNA isoform (+exon47), improved mouse survival and early motor development demonstrating a highly age-dependent operation window of $\alpha_1\text{ACT}$ in early life [44]. Importantly, $\alpha_1\text{ACT}$ was further shown to partially rescue the *CACNA1A* knockout phenotype associated with seizures, dystonia, ataxia, and death by postnatal days P18–P21 [45], at behavioral, histological, and electrophysiological levels [44]. These results demonstrate that both gene products, the ion channel and a nuclear protein $\alpha_1\text{ACT}$, play an important role in neuronal development and that in the case of perinatally decreased *CACNA1A* gene expression, the reintroduction of $\alpha_1\text{ACT}$ might be a potential early intervention therapy [44]. Taken together with the results from $\text{Ca}_V1.2$ and recent reports on C-terminal proteins identified across all functional VGCC classes (also $\text{Ca}_V1.3$ [46] and $\text{Ca}_V3.2$ [44]), it seems likely that the bicistronic expression of calcium channel proteins might be conserved across the gene family, even if a nuclear protein has not been documented for all channel isoforms, yet, and the nature of its expression mechanism is currently not fully elucidated.

Notably, not only intracellular domains of the VGCC pore have been identified to participate in transcriptional regulation, but also some isoforms of the auxiliary $\text{Ca}_V\beta$ subunit of the VGCC complex have been found in the nucleus. This intracellular family of VGCC subunits is widely known to support the trafficking and expression of functional VGCCs. Four isoforms of the $\text{Ca}_V\beta$ subunit are described (β_1 – β_4), each having different splice variants that might interact with any α_1 channel isoform in a tissue-dependent manner [11,47]. In addition to their essential effect on the forward trafficking of VGCCs [48,49], β subunits can also modulate the channel's kinetics, reported as a shift of the activation potential and raise of the opening probability of HVA channels resulting in larger current densities [14,50,51]. More surprisingly, several studies uncovered a calcium channel-independent function of β_4 which has been shown to translocate to the nucleus and might be directly

326  J. HECK ET AL.

involved in activity-dependent gene regulation. At first, Hibino and colleagues have described an atypical short splice variant of the β_4 subunit, namely β_{4C} , to directly interact with the chromo shadow domain of chromobox protein 2/heterochromatin protein 1 γ (CHCB2/HP1 γ), a nuclear protein involved in the epigenetic control of gene regulation and gene silencing. While having only slight effects on channel activation and inactivation kinetics, the co-expression of β_{4C} with CHCB2/HP1 γ fosters the recruitment of β_{4C} to the nuclei of mammalian cells and significantly reduces its transcriptional repression activity [52]. Despite some controversial results about the molecular underpinnings, a number of studies have now confirmed the nuclear targeting of various β_4 variants [52–55] and their direct involvement in gene regulation via interactions with proteins of the epigenetic machinery such as HP1s [52,56] or the regulatory subunit of protein phosphatases-2A [57,58]. Notably, the subcellular localization and thus the function of β_4 , either as a VGCC channel subunit or transcription regulator, was shown to be under the control of electrical activity and Ca^{2+} influx [54,57]. Subramanyam et al. further interpret this activity-dependent shuttling of β_{4b} into and out of the nucleus, and probably its switch between two independent physiological functions, as a possible mechanism of VGCCs to communicate their state of activity to the nucleus. Reconstitution experiments performed on cultured hippocampal neurons and cerebellar granule cells prepared from E17 lethargic (β_4 -null) mice have shown that the extent of β_4 nuclear targeting significantly varied for the tested β_4 splice variants which localized in neuronal nuclei with a rank order of $\beta_{4b} > \beta_{4a} > \beta_{4c}$ [55]. The differential subcellular distribution of β_4 splice variants suggests that they might regulate distinct genetic programs. Indeed, Etemad and colleagues report that the gene regulatory power of β_4 splice variants correlates with their nuclear-targeting properties. However, they further point out that the nature of regulated genes, which are mainly implicated in cellular signaling, membrane/vesicle transport, and neuronal development, is quite similar for the tested β_4 splice variants [55]. This could indeed

indicate an identical gene regulatory mechanism but remains to be explored in more detail.

$\alpha_2\delta$ subunits are many-sided extracellular interaction partners involved in synaptogenesis

In the extracellular space, VGCCs are represented by the auxiliary $\alpha_2\delta$ subunits that are attached to the outer loops of the α_1 subunits. To date, four $\alpha_2\delta$ isoforms ($\alpha_2\delta_1$ - $\alpha_2\delta_4$), encoded by the *CACNA2D1*-*CACNA2D4* genes, have been identified [13,14]. Being transcribed from a single gene [59], the $\alpha_2\delta$ protein undergoes post-translational proteolytic cleavage into α_2 and δ polypeptides [60] that remain linked via disulfide bonds [61]. Although it is generally assumed that every $\alpha_2\delta$ isoform can associate with any HVA α_1 pore-forming subunit, recent findings suggest distinct α_1 -preferences for some $\alpha_2\delta$ isoforms [62–65]. Hence, the observed differences in the distribution and expression levels of the individual $\alpha_2\delta$ isoforms across tissues and brain regions [66–71] might reflect such preferential interaction between $\alpha_2\delta$ and α_1 subunits. Experimental and clinical data on $\alpha_2\delta$ knockouts or mutations in $\alpha_2\delta$ genes revealed their important role for the development of neuronal networks and establishment of excitation-to-inhibition balance. In particular, genetic aberrations in *CACNA2D1* and *CACNA2D2* in humans are associated with a developmental delay, mental disability and symptomatic epilepsy [72,73]. In several studies of normotypic and autistic individuals, mutations in *CACNA2D3* were consistently identified as a risk factor for autism spectrum disorders [74]. In the last few years, several new interaction partners of $\alpha_2\delta$ subunits were identified, including thrombospondin [75], prion protein [76], LRP1 [77], BK channels [78], NMDA receptors [79], and α -neurexin [62,63]. Given the wide range of possible interactions, the idea that $\alpha_2\delta$ subunits can exert calcium channel-independent functions is increasingly gaining favor (Fig.3).

One of the most intriguing aspects related to such autonomous functions of $\alpha_2\delta$ subunits is their ability to trigger synaptogenesis in developing neurons. The $\alpha_2\delta_1$ subunit was shown to induce glutamatergic synapse formation in murine neurons through a process requiring interaction with

Figure 2. VGCCs participate in gene regulation.

Besides Ca^{2+} -dependent signaling cascades activating NFAT, CREB, or DREAM, VGCC β_4 subunits (A, left) and α_1 C-terminal domains (B, right) also act as transcription factors. A) β_4 splice variants interact with proteins of the epigenetic machinery such as HP1s or the B56 δ regulatory subunit of protein phosphatase-2A (PP2A) and translocate to the nucleus with a rank order of $\beta_{4b} > \beta_{4a} > \beta_{4c}$. B) CCAT and $\alpha_1\text{ACT}$ are fragments directly derived from the carboxyl-terminus of the pore-forming α_1 subunit of $\text{Ca}_v1.2$ and $\text{Ca}_v2.1$ channels, respectively. Their expression via an internal ribosomal entry site (IRES) or an unknown exonic promoter is controversially discussed. They have been shown to translocate to the nucleus and regulate gene activity associated with neurodevelopment and synaptic transmission. Modelled after Barbado et al. 2009³² and Tadmouri et al. 2012⁵⁷.

thrombospondins, extracellular matrix proteins released by young astrocytes [75]. Similarly, *straightjacket* (the ortholog of $\alpha_2\delta_3$) was reported to be essential for the development of excitatory synaptic boutons in *Drosophila*, with the extracellular α_2 peptide chain being necessary and sufficient for bouton formation [80]. The finding of Kurshan and colleagues that the synapse establishment was significantly impaired upon deletion of

straightjacket, but was not affected by the knock-out of the pore-forming subunit *cacophony* [80], provided one of the first pieces of evidence that synaptogenic function of $\alpha_2\delta$ subunits is independent of the α_1 subunit. A more recent report provided further compelling evidence for the channel-independent action of $\alpha_2\delta$ subunits on the formation of presynaptic release machinery and transsynaptic organization. In cultured

Figure 3. Channel-independent functions of the auxiliary $\alpha_2\delta$ subunit.

A) Excitatory and inhibitory synaptogenesis: As interaction partners of thrombospondins, $\alpha_2\delta$ s were shown to foster glutamatergic synapse formation. Further, $\alpha_2\delta$ subunits participate in GABAergic synaptogenesis. B) Transsynaptic signaling: $\alpha_2\delta$ subunits interact with α -neurexin, which is involved in the formation of transsynaptic complexes supporting synapse specification, establishment, maturation, and plasticity. C) Competition of other interaction partners, like the large conductance (big) potassium (BK) α subunit, for $\alpha_2\delta$.

hippocampal neurons and at the calyx of Held, triple knockout of $Ca_v2.1$, $Ca_v2.2$, and $Ca_v2.3$ strongly impaired evoked vesicle release but did not alter the structure of presynaptic terminals or transsynaptic organization [81]. Importantly, the localization of the $\alpha_2\delta_1$ in nerve terminals was not affected by the knockout of Ca_v2 channels as compared to control neurons, hence demonstrating that the synaptic localization of the $\alpha_2\delta_1$ is independent of the channel pore [81]. Furthermore, the total deletion of $\alpha_2\delta$ subunits in hippocampal neurons supported their relevance as a nucleation point for the formation of glutamatergic synapses [82]. Consistent with the role of $\alpha_2\delta_1$ subunits in glutamatergic synaptogenesis, the overexpression of $\alpha_2\delta_1$ in adult mice leads to cortical hyperexcitability, epileptiform activity, and an increased glutamatergic synaptic density [83], while a significant decrease in the number of excitatory synapses was shown for cortical neurons of $\alpha_2\delta_1$ knockout mice [84]. We have recently demonstrated that $\alpha_2\delta$ subunits can trigger the formation of not only excitatory, but also

inhibitory synapses in an isoform-specific manner [64]. While $\alpha_2\delta_1$ subunits selectively improved neurotransmitter release in glutamatergic synapses, the upregulation of the $\alpha_2\delta_3$, but not $\alpha_2\delta_1$, resulted in a significantly higher density of GABAergic synapses and facilitated both the axonal growth in GAD67-positive interneurons and spontaneous GABA release during early development [64]. Although modulatory effects on the channel pore cannot be completely ruled out, the expression, surface delivery, and major current properties of $Ca_v2.1$ and $Ca_v2.2$ channels were not affected by association with either $\alpha_2\delta_1$ or $\alpha_2\delta_3$ in heterologous expression systems [64].

A strong argument for the autonomous function of $\alpha_2\delta$ subunits is the plurality of their additional interaction partners. At the nanoscale organization of a synapse, their interaction of $\alpha_2\delta$ subunits with the synaptic cell adhesion molecule α -neurexin might be particularly interesting in the context of transcellular units, so-called nanocolumns [85,86]. These structures have been recently reported to align the presynaptic nerve terminal,

synaptic cleft, and postsynaptic compartment fostering efficient neurotransmission [85,86]. Similarly to $\alpha_2\delta$ subunits, α -neurexins exhibit a wide array of potential binding partners, including the postsynaptic neuroligin [87,88], neurexophilin [89], dystroglycan [90], LRRTM proteins [91,92], and cerebellin [93]. The complex formed by neurexin isoforms and neuroligins, for example, has been described as a transsynaptic assembly found at excitatory and inhibitory synapses that is involved in synapse specification, establishment, maturation, and plasticity [94]. Notably, Tong and colleagues have reported a selective interaction of the $\alpha_2\delta_3$ protein with neurexin1 α [62]. Since the confirmation of a specific association between $\alpha_2\delta$ isoforms and α -neurexin failed in overexpression experiments [63], the physiological interaction could be regulated rather via a cell type- or synapse-specific expression of these molecules than selective binding mechanisms. It is also conceivable that slight differences in the binding affinities can dynamically influence these molecular interactions. This could transiently modulate the calcium channel properties and, in turn, synaptic transmission and plasticity in an activity- or synapse-specific manner. Indeed, other partners, besides α -neurexin, e.g. BK potassium channels [80], have been also described to compete with the channel pore for the $\alpha_2\delta$ subunits [78]. Moreover, the channel-to- $\alpha_2\delta$ coupling is expected to be rather loose [95–97] and the analysis of surface dynamics of the $\alpha_2\delta_1$ subunits and various α_1 proteins further revealed, apart from a pool of $\alpha_2\delta_1$ bound to the channel, two subpopulations of the $\alpha_2\delta_1$ and α_1 subunits that are not interacting with each other [98]. Whether the dissociation of the $\alpha_2\delta$ subunit from the channel pore located in the plasma membrane has direct consequences on the channel gating, stability or turn-over rates has been discussed in some studies but requires more attention to resolve the molecular mechanism [78,99,100]. Besides gating or stability effects on the channel, changes in channel positioning or in the multi-subunit complex organization could also be possible.

To summarize, the VGCC pore-forming subunit as well as the auxiliary β and $\alpha_2\delta$ subunits play an essential role in voltage-induced calcium release, gene regulation, neuronal synaptogenesis,

and transsynaptic signaling, which do not necessarily involve the Ca^{2+} transients of the channel complexes. The modular expression as multi-subunit complexes provides a first basis for the diversity and functional range of these molecules. We aim to further develop the idea that the functional diversity of VGCCs could not only arise from different basic channel kinetic and ion-conducting properties but rather from variations in their interaction partners or molecular environment. Some interesting findings pointing in this direction come from studies of alternative splice variants of VGCCs, which will be in the focus of the last section of this review.

Alternative splicing: How VGCC transcript variants shape neuronal phenotypes or vice versa?

Alternative splicing is crucial for increasing the proteomic diversity of the finite number of genes, which allows for a massive expansion of the coding power of the metazoan genome [101,102]. To explain the high functional diversity of neuronal phenotypes observed in distinct brain areas and over development, many studies have focused on the regulatory role of alternative splicing for molecules involved in neurotransmission, including large multi exon ion channels and postsynaptic receptors [103–108]. Nowadays, genome-wide analysis of splicing events strongly supports the idea of specialized splicing patterns in distinct neuronal phenotypes [109–111]. In the case of VGCCs, nine of the ten genes that encode the pore-forming α_1 calcium channel subunit are expressed in the mammalian brain, and each α_1 subunit contains multiple sites that are hot-spots for splicing events [103,112]. However, whether VGCCs are indeed spliced in a cell type-specific manner has not been comprehensively assessed, yet. For a first estimation, we have analyzed raw sequencing data generated by Furlanis and colleagues (accession code: GSE133291 [110]; Fig. 4) from ribosome-associated transcript isoforms in genetically defined neuron types of the mouse forebrain. The data indicate that some classes of neurons indeed stand out for the splicing events of VGCCs,

annotated to date. Especially the class of parvalbumin (PV)-positive cells, which have been described as fast-spiking GABAergic interneurons [113], show a distinct VGCC splicing pattern (Fig. 4C). Hence, there might be a link between neuronal cell identity and VGCC splicing. The structural changes induced by alternative splicing might affect channel gating and conductance, which then leads to different functional properties of neuronal phenotypes. There is an extensive literature accumulated over the last decades that clearly demonstrates major effects of VGCCs' splicing on the channel's pharmacology, gating, surface expression, but also on its molecular interactions [103,114,115]. Here, we want to present some examples, showing that alternative splicing has no direct consequence on the channel gating but rather affects their coupling to downstream interaction partners triggering different signaling pathways.

One interesting VGCC splice event is the usage of two mutually exclusive exons 37a and 37b found in the C-terminus of the neuronal Ca_v2 calcium channels ($\text{Ca}_v2.1$ [123], $\text{Ca}_v2.2$ [124] and $\text{Ca}_v2.3$ [116]). Independent studies have shown that the splicing of exons 37a and 37b generates two variants, EFa (or 37a) or EFb (or 37b), of the EF-hand-like Ca^{2+} -binding motif that acts as a molecular switch for calcium-dependent facilitation and might modulate different neuronal phenotypes in a spatiotemporal manner [105,123–127]. The recent analysis of RNA-seq data obtained from specialized neuronal cell types mapped the differential usage of exon37 for $\text{Ca}_v2.1$ channels across excitatory and inhibitory neurons [111]. Huntley et al. confirmed that the mutually exclusive usage of exon37 correlates with opposite short-term plasticity behavior observed for principal excitatory neurons versus inhibitory cells (like PV interneurons). These results are in line with the electrophysiological characterization of rat hippocampal neurons where the expression of $\text{Ca}_v2.1$ [EFa] was shown to promote synaptic depression, while $\text{Ca}_v2.1$ [EFb] favored synaptic facilitation [105]. Thalhammer and colleagues have further demonstrated that $\text{Ca}_v2.1$ [EFa] is more tightly coupled to presynaptic scaffold proteins and the neurotransmitter release machinery when compared to $\text{Ca}_v2.1$ [EFb], which is

characterized by a rather loose coupling [105]. Although a contribution of differing biophysical properties for $\text{Ca}_v2.1$ [EFa] and $\text{Ca}_v2.1$ [EFb] cannot be excluded, the authors pointed out that the variation of the synaptic efficacy between these splice variants is likely due to a differential organization and molecular coupling at the presynaptic site [105]. This suggests that the tighter coupling of $\text{Ca}_v2.1$ [EFa], preferentially expressed in PV neurons, might be necessary to define the PV phenotype, whereas excitatory neurons use the $\text{Ca}_v2.1$ [EFb] variant. As previously mentioned, the mutually exclusive usage of exon37 is conserved across neuronal Ca_v2 channels [116,123,124]. For $\text{Ca}_v2.2$ channels, it has been shown that alternative splicing of the exon37 plays an important role in voltage-independent inhibition via G proteins. The inclusion of exon37a results in the expression of a tyrosine residue (Y1747), which is absent in exon37b, that triggers a voltage-independent inhibitory pathway that increases the sensitivity of $\text{Ca}_v2.2$ channels to opiates and the inhibitory neurotransmitter GABA [128]. In a following study, the Lipscombe laboratory has further demonstrated the importance of activity-independent inhibition of $\text{Ca}_v2.2$ channels expressing exon37a for its function in nociceptors and morphine analgesia sensitivity *in vivo*, and thus the relevance for the pain pathway [129].

As already indicated above, the C-terminus of neuronal VGCCs has been described for its central role for the channel's synaptic targeting and organization [108,130], interaction with scaffolding proteins [105,131–135], G protein signaling [128,129], gating [112,125,136–139], and consequently, for synaptic transmission and short-term plasticity [105,108]. Therefore, we now want to pay attention to another splice event in the distal part of the VGCC's C-terminus that critically affects the length and binding sites expressed by this important structure. The expression of truncated VGCCs arising from alternative splicing events has been reported across neuronal calcium channel isoforms [114,140]. In the case of $\text{Ca}_v2.1$ channels, a premature stop codon results in the expression of a channel variant lacking exon47, termed $\Delta 47$, that exhibits a 150–250 amino acids (depending on the species) shorter C-terminus compared to the fully expressed exon 47 (+47) [112,141]. This

Figure 4. VGCC genes are spliced differently across neuronal cell types.

A) Schematic overview representing different neuronal cell populations included in the RNA sequencing data (data is publicly available; accession code: GSE133291^[110]). The scheme was adapted from Furlanis and colleagues. The color-code for the cell types is used in B. CamK2= Ca^{2+} /calmodulin-dependent protein kinase II; Grik4= glutamate receptor, ionotropic, kainite 4; PV= parvalbumin; Scnn1a= α subunit of the epithelial sodium channel ENaC; SST=somatostatin; VIP= vasoactive intestinal peptide. B) The principal component analysis (PCA) of the gene expression demonstrates a differential regulation of VGCC genes across excitatory and inhibitory neuronal cell types. Especially, the cluster of PV interneurons localizes with significant gap to other neuron types on principal component 1, which explains roughly fifty percent of the observed variance. Data analysis: The fastq-files were mapped to the mm10 reference genome using STAR^[117]. The PCA was performed with DESeq2 in R^[118,119] and plotted with ggplot2^[120]. C) Heatmap of alternatively spliced transcripts of VGCC genes. We have analyzed the occurrence of the following splice events: cassette exon (CE), mutually exclusive exon (MX), retained intron (RI), alternative 5' splice-site (A5), alternative 3' splice-site (A3) and alternative first exon (AF), schematically shown in the lower part of C. Only those events that show a significant variance between the samples (ANOVA p-value < 0.01) were included. Overall, a difference between the PV neurons and the remaining samples in the splice patterns for the VGCC genes can be observed (e.g. *CACNA1A* MX(2), *CACNB1* CE(4) or *CANB3* MX (5)). Since the exon numbering depends on the transcript variant of a respective gene, the exact position for the splice variants (for instance, the start and end coordinates of the included exon) of the heatmap are listed here: *CACNA1A*: CE (1) chr8:84601756–84601821, MX (2) chr8:84614695–84614791, *CACNA1B*: A3 (1) chr2:4718122, CE (2) chr2:24642853–24642858, CE (3) chr2:24656711–24656722, CE (4) chr2:24682976–24683038, *CACNA1C*: AF (1) chr6:119196231–119196093, MX (2) chr6:118637730–118637813, *CACNA1D*: A3 (1) chr14:30129848, CE (2) chr14:30129789–30129848, CE (3) chr14:30137041–30137124, MX (4) chr14:30089296–30089379, MX (5) chr14:30107653–30107712, MX (6) chr14:30171296–30171399, RI (7) chr14:30128798–30129789, *CACNA1E*: A5 (1)chr1:154471338, CE (2) chr1:154404885–154405013, MX (3) chr1:154416061–154416157, *CACNA1G*: CE (1) chr11:94423671–94423724, CE (2) chr11:94439709–94439777, *CACNA2D1*: CE (1) chr5:16322539–16322595, CE (2) chr5:16341990–16342010, *CACNB1*:A5 (1) chr11:98010004, AF (2) chr11:98023034–98022887, CE (3) chr11:98010627–98010646, CE (4) chr11:98011343–98011497, MX (5) chr11:98010627–98010646, *CACNB2*: A5 (1) chr2:4971646, AF (2) chr2:4739216–14739763,AF (3) chr2:4763129–14763992, MX (4) chr2:14967942–14968075, *CACNB3*: A3 (1)chr15:98640686, AF (2) chr15:98631805–98631931, AF (3) chr15:98632376–98632520, CE (4) chr15:98640959–98640978, MX (5) chr15:98640959–98640978, *CACNB4*: AF (1)chr2:52676582–52676271, AF (2) chr2:52676831–52676271, CE (3) chr2:52556202–52556361, MX (4) chr2:52465894–52465913, *CACNG5*: AF (1) chr11:107915055–107914900. For this analysis, the fastq-files were mapped to the referencegenome (mm10) with Salmon^[121] and the percentage-spliced in (PSI) values were computed using SUPPA2^[122].

332  J. HECK ET AL.

truncation was shown to affect the channel's trafficking, its molecular arrangement, as well as synaptic transmission properties including short-term plasticity [108,142]. However, only mild effects on the channel kinetics have been reported so far [108,142]. Moreover, a study by Aikawa et al. using a knockin mouse line, which exclusively expresses $Ca_v2.1_{\Delta 47}$ ($CACNA1A^{CtmKO/CtmKO}$), has shown that in cerebellar Purkinje cells, exon47 was not required to maintain such basic channel electrophysiological properties as current density-voltage relationships and channel inactivation. Instead, in the cerebellum, exon47 has a more important role in establishing channel interactions with scaffold proteins such as RIM-binding protein 2 and the auxiliary subunit β_4 . Surprisingly, the absence of exon47 did not only reduce interactions to scaffold proteins but also promoted the binding to $GABA_{B2}$, a principal subunit of the G protein-coupled receptor for GABA, in the cerebellum of $CACNA1A^{CtmKO/CtmKO}$ mice. This enhancement of $Ca_v2.1$ - $GABA_{B2}$ interaction might contribute to the pathogenesis of absence seizures and motor incoordination observed in these animals [143–147].

These examples demonstrate that changes in the structure of VGCCs induced by splicing events also affect their interaction to partner molecules and suggest that significant functional implications cannot be reduced to their ionic activity.

Outlook and perspectives

Although this review cannot fully capture the functional range of VGCCs, we aimed to draw attention to some side functions of VGCCs that go beyond their classical role as ion channels to induce local Ca^{2+} nanodomains necessary for neurotransmission or downstream Ca^{2+} signaling pathways. When associated with ryanodine receptors, VGCCs contribute to a functional complex to trigger voltage-induced Ca^{2+} release from intracellular stores, a process that is independent of their ionic activity. Further, VGCC auxiliary subunits as well as C-terminal domains of the α_1 channel pore participate in gene regulation. Their activity- and Ca^{2+} -dependent subcellular shuttling implicate a pathway how VGCCs communicate their own activity status to the nucleus and integrate transient Ca^{2+} signaling

into longer-lasting transcriptional processes. These transcriptomic alterations should be considered especially when evaluating the phenotype of channelopathies, where most of the studies have primarily focused on explaining the pathological consequences based on the loss or gain of calcium channel function so far. Moreover, we have shown that $\alpha_2\delta$ auxiliary subunits are directly involved into neuronal network development and maintenance by fostering excitatory and inhibitory synaptogenesis and transsynaptic signaling. We have introduced some examples where structural changes in critical VGCC domains result in distinct synaptic plasticity behaviors and contribute, at least to some extent, to the specification of neuronal phenotypes. Notably, these changes in the channel structure do not necessarily involve differences in basic channel gating but might rather involve different protein environments or downstream pathways. Considering the many interaction partners of VGCCs, and from a molecular dynamics point of view, we want to point out the possibility that these large molecules could also serve as seeding points for molecular interactions. The question remains open at this point to what extent VGCCs can shape their environment by acting as a basic element bringing together important signaling molecules or how specific interaction partners that are present, e.g. in distinct neuronal phenotypes, regulate VGCCs' functional diversity.

Acknowledgements

We thank the Scheiffele Lab from the University of Basel for sharing the extensive dataset of ribosome-associated mRNAs from major neuron classes published in Furlanis et al. 2019 and for interesting discussions about neuronal cell class-specific alternative splicing.

HVA	high voltage-activated
IRES	internal ribosomal entry site
Kv	voltage-gated potassium channels
KCa	calcium-activated potassium channels
KIKO	knockin-knockout compound heterozygote mice
LRRM	leucine-rich repeat transmembrane proteins
mEPSCs	miniature excitatory postsynaptic currents
mIPSCs	miniature inhibitory postsynaptic currents
MX	mutually exclusive exon
NFAT	nuclear factor of activated T-cells
NMDA	N-methyl-D-aspartate
ORAI	calcium release-activated calcium channel protein
PCA	principal component analysis
PP2A	protein phosphatases 2A
PSI	percentage spliced in
PV	parvalbumin
RI	retained intron
RNA-seq	high-throughput RNA sequencing
RyR	ryanodine receptor
SCA6	spinocerebellar ataxia type 6
Scnn1a	α subunit of the epithelial sodium channel ENaC
SST	somatostatin
Tet	tetracycline
TRP	transient receptor potential channels
VGCC	voltage-gated calcium channel
VIP	vasoactive intestinal peptide

Funding

This work was supported by the Schram Foundation (Arthur Bikbaev), the Carl-Zeiss Foundation (Stephan Weißbach), and internal university research funding of the Johannes Gutenberg-University (Jennifer Heck).

10

11 **Keywords:** glutamate imaging, functional imaging, iGluSnFR, denoising, deep
12 learning

13 Highlights

- 14 - Neuroimage Denoiser is a deep learning framework to remove noise from
15 functional microscopic recordings, particularly trained and tested for glutamate
16 imaging
- 17 - Neuroimage Denoiser balances the removal of noise while preserving the
18 amplitude of responses
- 19 - Neuroimage Denoiser operates without re-training for different sensors (when
20 the localization is similar) and recording frequencies

21 Motivation

22 Accurate measurements of neuronal activity through functional imaging are critical in
23 understanding mechanisms of synaptic plasticity and learning concerning changes in
24 the molecular composition of single synapses. Traditional denoising methods, such as
25 Gaussian or Median filters, indiscriminately smooth entire recordings, reducing
26 temporal and spatial resolutions considerably. Existing frameworks are not suited to
27 remove noise from glutamate recordings due to the fast dynamics of the sensor.
28 Therefore, a specialized tool for the challenges imposed by glutamate recordings, i.e.
29 faster dynamics, and synaptic localization, is needed.

30 Summary

31 We developed Neuroimage Denoiser, a novel U-Net-based model that effectively
32 removes noise from microscopic recordings of transient local fluorescent signals. The
33 model makes the denoising process independent of the recording frequency and the
34 kinetics of the sensor used. The framework is easy to use for denoising and training

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. 35 and has minimal hardware requirements, thus, making it accessible for an average
36 laboratory to create a custom version specific to their experimental setup. Neuroimage
37 Denoiser significantly enhances the quality of functional microscopy recordings by
38 effectively removing noise, thereby facilitating a more accurate and reliable analysis of
39 neural activity.

40 Introduction

41 Noise is a pervasive phenomenon impacting all experimental systems used in
42 neuroscience. Accurate measurement of neuronal activity is crucial for understanding
43 neuronal function, yet noise in imaging systems can severely distort data¹. With the
44 development of genetically encoded calcium or neurotransmitter sensors, the
45 possibility reading the activity of neuronal subcellular compartments like synapses
46 became feasible, based on fast time-lapse fluorescent imaging. In camera-based
47 setups, noise affects pixels individually without any spatiotemporal relations, often
48 uneven distributed over the field of view. However, the signal from fluorescent reporters
49 that indicates neuronal activity in synapses or somata exhibits a high spatiotemporal
50 correlation.

51 Traditional methods, such as Gaussian or Median filters, can be used to remove noise
52 from microscopic recordings. While effective to some extent, these filters
53 indiscriminately smooth the entire image, leading to reduced temporal and spatial
54 resolutions². Additionally, the manual selection of filter parameters can be labor-
55 intensive and subjective, often resulting in suboptimal noise reduction.

56 There has been a considerable effort to remove noise from calcium imaging data and
57 several frameworks have been proposed³⁻⁷. Notably, Lecoq et al. (2018) developed
58 the deep-learning approach DeepInterpolation³, a U-Net architecture framework that
59 effectively reduces noise in various biological recordings, including somatic calcium
60 imaging, fMRI, and MEA recordings. DeepInterpolation leverages the data's inherent
61 spatial and temporal relationships to distinguish between true signals and noise,
62 offering a more sophisticated and automated approach to noise reduction³.

63 However, commonly used sensors like somatic GCaMP6f, which measure calcium
64 influx, exhibit slower dynamics compared to diffusion-dominated local release of
65 neurotransmitters. Monitoring the synaptic glutamate release needs considerably
66 higher spatial and temporal resolution⁸, accessible with camera-based approaches.
67 This can be challenging for a tool that was particularly trained on data acquired using
68 sensors with vastly slower kinetics, i.e. TITL-GCaMP6f, and TIT2L-GCaMP6f-ICL-
69 tTA^{2,9,10}. The glutamate sensor iGluSnFR3.v857.SGZ¹¹ fluoresces upon glutamate
70 release in the synaptic cleft and subsequent binding to the sensor, providing a much
71 faster signal directly related to neuronal communication⁸. These synaptic signals
72 originate from the fusion of individual transmitter vesicles within the presynaptic
73 membrane and are accompanied by higher background noise compared to the larger
74 somatic calcium signals.

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under a [CC-BY-NC 4.0 International license](#).

75 To address these specific challenges, we developed Neuroimage Denoiser, a novel
76 model that effectively removes independent noise from microscopic recordings. Unlike
77 traditional methods, the training and architecture of Neuroimage Denoiser makes the
78 denoising process independent of the recording frequency and the kinetics of the
79 sensor used. This flexibility sets Neuroimage Denoiser apart from previous methods
80 and makes it a versatile tool for various experimental setups, including fast calcium
81 imaging.

82 Neuroimage Denoiser has minimal hardware requirements, making it accessible for
83 many laboratories to create a custom version tailored to their specific experimental
84 setup. Neuroimage Denoiser enables researchers to obtain high-quality, noise-
85 reduced data without the need for extensive computational resources or expertise.

86 Material and Methods

87 Primary hippocampal mouse cultures

88 Primary mouse hippocampal cultures were generated from newborn pups¹². Animals
89 were sacrificed according to the European and local government (Rheinland-Pfalz,
90 Germany) regulations for animal welfare. After dissociation with trypsin (Thermo Fisher
91 Scientific; Cat#: 15090-046), cells were plated on poly-L-lysine-coated 18 mm glass
92 coverslips with a density of 70,000 cells per coverslip. After 1 h incubation in
93 Dulbecco's Modified Eagle Medium (Thermo Fisher, Gibco; Cat#: 41966-029/D6429)
94 supplemented with 10% fetal bovine serum and 0.5% glutamate at 37°C, coverslips
95 were transferred to 12-well plates containing 1mL of growth medium composed of
96 Neurobasal-A (Thermo Fisher, Gibco; Cat#: 12349-015) with 2% GlutaMax (Thermo
97 Fisher, Gibco; Cat#: 35050-038), 2% B27 (Thermo Fisher, Gibco; Cat#: 17504-044),
98 0.1 M sodium pyruvate (MERK, Sigma; Cat#: S8636). Cultures were maintained in a
99 humidified incubator with an atmosphere of 95 % air and 5 % CO₂ at 37°C.

100 At DIV3-5 neurons were transfected with glutamate sensor iGluSnFR3.v857.SGZ
101 (Addgene; Cat#: 178330)¹¹ to perform functional imaging experiments, using the
102 calcium phosphate method. To validate the generalizability of the model, one culture
103 was infected with iGluSnFR.S72A (Addgene; Cat#: 106176)¹³. Briefly, the neuron's
104 growth medium was exchanged with 1 mL of pre-warmed Neurobasal-A medium, and
105 the original medium was stored and kept at 37°C. In the meantime, per 18 mm
106 coverslip, 30 μ L of transfection buffer containing in mM: 274 NaCl, 9.5 KCl, 1.4
107 Na₂HPO₄, 15 Glucose, 15 HEPES, pH 7.14 were added to a solution containing 3 μ g
108 of DNA and 2 M CaCl₂ and 24 μ L of H₂O (q.s. 30 μ L). The resulting DNA/CaPO₄ mix
109 was incubated for 20 min at RT and then added in a proportion of 60 of mix per well.
110 Incubation on neurons was maintained at 37°C until precipitate formation (40 min).
111 Following DNA/CaPO₄ incubation, neurons were washed two times for 5 min with 1X
112 HBS buffer containing in mM: 137 NaCl, 4.75 KCl, 0.7 Na₂HPO₄, 7.5 Glucose, 7.5
113 HEPES, pH 6.9 and for one time for 5 min with Neurobasal-A medium. Following the

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under a [CC-BY-NC 4.0 International license](#).

114 washing steps, the original growth medium was added, and neurons were stored in the
115 incubator at 37°C until live imaging experiments were performed at DIV16 - 19.

116

117 Functional Imaging

118 All live experiments were conducted on hippocampal cultures 16 - 19 DIV at 37°C
119 within a whole microscope incubator. Neurons were perfused with extracellular solution
120 containing (in mM): 145 NaCl, 2.5 KCl, 10 HEPES, and 10 D-glucose 2 MgCl₂, 2 CaCl₂
121 (pH 7.4). Network activity was suppressed by adding 10 μM CNQX (Tocris; Cat#: 1045)
122 and 10 μM D-AP5 (Tocris; Cat#: 0106) to the extracellular solution as indicated for the
123 respective experiment. Experiments were performed with an inverted total internal
124 reflection fluorescence (TIRF) setup composed of the eclipse Ti microscope (Nikon)
125 equipped with a 60 x Apo TIRF oil objective (1.49 NA; Nikon). Fluorescence was
126 excited with a combined laser system (Coherent; MPB Communications Inc.). Images
127 were captured by a scientific CMOS camera (ORCA-Fusion C14440-20UP,
128 Hamamatsu) at frame rates between 100 to 1000 Hz controlled by NIS-Elements
129 Advanced Research acquisition software (Nikon). Electrical field stimulation was
130 carried out using two platinum electrodes placed on the coverslip at a 10 mm distance.
131 Extracellular stimulus sequences (0.9 ms; 50 mA; 1 s interval) were triggered by an
132 isolated pulse generator (A&M Systems, Model 2100) and delivered via a stimulus
133 isolator unit A385 (WPI). Images were acquired by image streaming for 2000 frames
134 at 100 Hz within a defined region of interest (ROI) 800 x 800 pixels (100 Hz acquisition
135 rate) or 250 x 250 pixels (1000 Hz acquisition rate) with a pixel size of 72nm. Triggered
136 electrical field stimulation was used to elicit 20 action-potential-like stimuli.

137 Synaptic ROI and Threshold

138 Circular synaptic ROIs were selected manually using Fiji (version 1.54f)¹⁴ and set to a
139 diameter of 9 pixels. The average traces along the z-axis of the synapses were
140 extracted by either Fiji (version 1.54f)¹⁴ or Python (version 3.10.14)¹⁵ with roifile
141 (version v2024.3.29)¹⁶.

142 On the average traces, the threshold was computed using numpy (version 1.26.4)¹⁷
143 based on the baseline frames up to the first stimulation, using the formula:

$$144 \quad \text{Threshold}(x) = \text{mean}(x) + \text{threshold}_{\text{mult}} * \text{std}(x)$$

145 Whenever the average trace crossed the computed threshold (set by $\text{threshold}_{\text{mult}}$),
146 this was considered to be a response.

147 Preparing Training Data

148 Training deep learning models is sensitive to imbalances between foreground and
149 background^{18,19}. The microscopic recording of synaptic glutamate responses is
150 dominated by background due to the small synapses that sparsely respond when
151 defining a responding synapse as foreground. Therefore, the available data is filtered
152 for active regions and frames to remove the background (Figure 1a). We transformed
153 our recording frames into activity maps to filter efficiently. First, the data is transformed

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC 4.0 International license.

154 by a pixel-wise rolling window (along 50 frames) z-normalization (Figure 1b). The
155 rolling window adapts for potential bleaching in the recording.

156
$$z\ score_{frame} = \frac{x_{frame} - \mu_{window_{start}:window_{end}}}{\sigma_{window_{start}:window_{end}}}$$

157 An activity map is calculated framewise and represents the maximum z-score within a
158 local region for each spatial position in each frame. Each frame is divided into crops of
159 a predefined size of 32 x 32 pixels to compute the activity map. A crop is assigned with
160 the maximum value of the kernel-averaged region, obtained by sliding a quadratic
161 kernel over the crop (step size 1) and computing the average intensity within that kernel
162 at each position (Figure 1c, right). The kernel size corresponds to the expected minimal
163 region of interest (ROI) size, reflecting the spatial extent of the structures under
164 investigation (6 pixels for synapses in our setup). The activity map effectively captures
165 and highlights regions exhibiting high-intensity fluctuations that are potential indicators
166 of neuronal activity, by assigning the maximum averaged kernel value to each crop.
167 Next, these activity maps are filtered for crops that exceed a minimum z-score of 3.
168 Subsequently, the pixel-wise z-score (without using a rolling window) is computed, and
169 the transformed crop is stored in an h5 file for training, using h5py (version 3.11.0).

170 Neuroimage Denoiser can be run on an entire directory storing multiple recordings and
171 will automatically prepare the training data without manual intervention. Additionally, a
172 memory-optimized version is implemented that necessitates less RAM at the cost of a
173 longer run-time.

174

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. 187 Model Architecture and Training

188 The U-Net model²⁰ is implemented in PyTorch (version 2.1.1.)²¹ with a single input and
189 output channel (Figure 1a). The U-Net architecture consists of an encoder and a

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC 4.0 International license.

190 decoder. The encoder comprises blocks containing two 2D convolutional layers with
 191 3x3 kernels, ReLU activation, and batch normalization, followed by a 2D max-pooling
 192 layer for downsampling. These blocks are referred to as down-blocks. Skip
 193 connections connect the corresponding down-blocks to the up-blocks in the decoder
 194 without any processing.

195 The decoder comprises up-blocks, each consisting of a 2D transpose convolutional
 196 layer for upsampling, followed by a concatenation with the respective feature map from
 197 the corresponding down-block (skip connection). This concatenated output is then
 198 processed by two 2D convolutional layers with 3x3 kernels, ReLU activation, and batch
 199 normalization. The final layer is a 1x1 2D convolutional layer that maps the feature
 200 vector to the denoised image. This architecture allows the network to capture both local
 201 and global features, enabling accurate denoising of the input image. Using a fully
 202 convolutional model without dense layers allows flexible input image sizes during
 203 inference, limited only by GPU memory, overcoming fixed training input constraints.

204 Training is performed on z-transformed patches containing active synapses for one
 205 epoch using a batch size of 64, the ADAM optimizer with a learning rate of 0.0001, on
 206 a consumer-grade NVIDIA GeForce 2060 super graphics card with 8GB of vRAM. A
 207 grid search for the parameters listed in Table 1 was performed to find a suitable
 208 combination of parameters for the training. The model's objective is to reduce noise in
 209 the recordings while maintaining the integrity of the peak response amplitudes.

210 To evaluate the model's performance in preserving the amplitude of neural responses,
 211 regions of interest (ROIs) exhibiting clear stimulus-evoked responses were manually
 212 identified in the raw recorded data. The peak response amplitudes within these ROIs
 213 were measured following the presentation of a stimulus. After training the model, the
 214 same ROIs were analyzed in the denoised output, and the corresponding peak
 215 response amplitudes were extracted. The model's accuracy in preserving the response
 216 amplitudes is quantified by calculating the Mean Absolute Percentage Error (MAPE)
 217 using scikit-learn (version 1.5.0)²² between the raw and denoised peak amplitudes
 218 across all ROIs. The correlation between raw and denoised peak amplitudes was
 219 calculated using scipy²³.

$$220 \quad MAPE = 100 * \frac{1}{n} \sum_{t=1}^n \left| \frac{peak_t^{raw} - peak_t^{denoised}}{peak_t^{raw}} \right|$$

221 Additionally, it is crucial that the model efficiently removes noise from the microscopic
 222 recordings. This is measured by the standard deviation of non-responding sections of
 223 the recordings.

224 Both metrics (MAPE and standard deviation) are ranked, and a combined score is
 225 calculated. The best-performing model is selected based on the minimal combined
 226 score achieved (supplementary table 1).

$$227 \quad score = \frac{(Rank_{std} + 2 * Rank_{MAPE})}{3}$$

228

231 *the most effective configuration. The "Best performing Model" column lists the values that yielded the best*
 232 *performance based on the evaluation metrics.*

Parameter	Tested Variables	Best performing Model
Loss Function	L1, Smooth-L1, MSE, Huber	Smooth-L1
Use Gaussian Filter on y_{True}	True, False	True
Sigma Gaussian Filter	0.5, 1.0	1.0
Noise Center	0, 0.5, 1.0	0
Noise Scale	0.5, 1.0, 1.5, 2.0, 3.0	2.0

233

234 Inference/Denoising

235 The denoising (or inference) using Neuroimage Denoiser can be done on single
 236 images or entire directories containing multiple sub-directories while maintaining the
 237 original folder structure. The process is schematically visualized in Figure 1e. First, the
 238 input image is loaded in tiff or nd2 format using tiff file (version 2023.12.9)²⁴ or nd2
 239 (version 0.8.1) respectively and a z-normalization (along the time axis; no rolling
 240 window) is applied. The mean and standard deviation per pixel is temporarily saved.
 241 Neuroimage Denoiser performs the denoising on the z-normalized frames and
 242 afterward, the resulting frames are transformed back into intensity values using the
 243 saved mean and standard deviation. The denoised image is saved as a tiff file using
 244 tiff file (version 2023.12.9)²⁴.

245 Reimplementation of DeepInterpolation

246 To fairly compare the performance of DeepInterpolation³ with the approach of
 247 Neuroimage Denoiser, we re-implemented the model in PyTorch (version 2.1.1)²¹.
 248 Therefore, the model can be trained on crops of active synapses (32 x 32 pixels) and
 249 comparability was ensured. The number of frames before and after the target frames
 250 was reduced to five frames to account for the faster dynamics of glutamate sensors
 251 (Supplementary Figure 1a). The model was trained using the ADAM optimizer with an
 252 L1 loss function, and a learning rate of 0.0001 on an NVIDIA GeForce GTX2060 super
 253 graphics card.

254 Data Visualization

255 Data was visualized using Python (version 3.10.14)¹⁵, matplotlib (version 3.9.0)²⁵, and
 256 seaborn (version 0.13.2)²⁶. Schematic drawings were made using Adobe Illustrator.

257 Results

258 Denoising glutamate imaging data presents unique challenges compared to calcium
 259 imaging, as glutamate sensors are orders of magnitude faster and the synaptic
 260 localization results in considerably less foreground signal relative to somatic calcium
 261 recordings. Here, we present Neuroimage Denoiser, a U-Net-based imaging denoising

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC 4.0 International license.

262 tool (Figure 1a) specifically trained to remove noise from microscopic glutamate time-
263 series recordings.

264 To curate a balanced training dataset adjusted to the challenges posed by glutamate
265 imaging data, the recordings are automatically screened to identify frames and regions
266 exhibiting active synaptic signals (Figure 1a) in the training preparation step without
267 manual intervention. This screening can be adapted to different ROI sizes representing
268 the size in pixels of the biological structure where the sensor is localized. We set the
269 ROI size to 6 pixels to account for the size of synapses harboring the sensor in our
270 microscopic set-up.

271 Initially, we explored training a model in the style of DeepInterpolation³.
272 DeepInterpolation predicts a target frame based on a set number of frames preceding
273 and succeeding the target frame (n_{pre} , n_{post})³. To account for the fast dynamics of the
274 iGluSnFR3 sensor compared to Gcamp6f, we set $n_{pre} = 5$ and $n_{post} = 5$ and the model
275 predicts the target frame in the middle (Supplementary Figure 1a). However, this
276 temporal interpolation approach, while effective for slower calcium dynamics, did not
277 adequately preserve the fast glutamate response and led to artifacts in the amplitudes
278 (Supplementary Figure 1b).

279 Given the limitations of the DeepInterpolation strategy for capturing these rapid
280 synaptic signals, we turned to the Noise2Noise concept proposed by Lehtinen and
281 colleagues²⁷. Their work demonstrated image restoration without ground truth data by
282 training networks to distinguish signals from noise patterns by adding artificial noise to
283 noisy images. Leveraging this approach, Neuroimage Denoiser is trained according to
284 the Noise2Noise²⁷ method on individual frames and subsequently circumvents the
285 dependence on the recording frequency or the dynamics of the sensor. Therefore, a
286 trained model can be applied to a broad range of sensors that have similar localization
287 independently of the recording frequency.

288

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under a [CC-BY-NC 4.0 International license](#).

306 preservation (Supplementary Table 1). The selected model effectively removes noise
307 from the raw recording, both visually as measured in the z-profile of the synaptic ROI
308 (Figure 2b), while preserving the amplitudes well (Figure 2c), as evidenced by a
309 significant correlation between raw and denoised amplitudes ($R=0.9966$, $p < 0.0001$).
310 Neuroimage Denoiser demonstrates fast inference, as tested on three recordings of
311 1000 frames with varying spatial dimensions (50 to 800 pixels for x and y). The entire
312 process, including normalization and reverse normalization, as shown in Figure 1e,
313 requires between 0.0003 and 0.1519 seconds per frame (Figure 2d). Therefore,
314 denoising 800 x 800 pixels recording of the length of 1,000 frames takes ~152 seconds.

315

316 Neuroimage Denoiser enables precise Signal Localization across 317 diverse Recording Conditions

318 Only infrequent spontaneous activity can be observed when recording a neuronal
319 culture in the absence of electric stimulation. Specifically, it is challenging to
320 differentiate the components at complex synapses, which comprise an accumulation
321 of pre-synaptic inputs and post-synaptic receivers. These synapses often involve
322 multiple release sites in close proximity, and the released glutamate can diffuse from
323 its initial release site, leading to highly correlated signals at neighboring post-synaptic
324 sites (Figure 3a, left). However, the maximum localization of a spontaneous release
325 event indicates the release site. Due to the spatial proximity within these complex
326 synapses, identifying and differentiating post-synaptic receiving sites is difficult when
327 the signal is superimposed by noise (Figure 3a, top). After removing the noise using
328 Neuroimage Denoiser, each of the three distinct sites within the complex synapse
329 becomes visible and can be accurately localized (Figure 3a, bottom).

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. It is made available under aCC-BY-NC 4.0 International license.

330
 331 *Figure 3 a) Complex synapse with three sites that receive spontaneous input from different pre-synaptic sites.*
 332 *The top row shows the raw recording as it was acquired at the microscope and the bottom row shows the same*
 333 *frames denoised by Neuroimage Denoiser. The three different sites showing spontaneous activity are visible. The*
 334 *traces at these sites are highly correlated due to their proximity. b) Neuroimage Denoiser works on recordings*
 335 *acquired with very high recording frequencies (tested here with 1000Hz) although being trained on 100 Hz*
 336 *recordings exclusively.*

337 While Neuroimage Denoiser was trained exclusively on recordings done with 100 Hz,
 338 the model is capable of denoising recordings acquired at significantly higher acquisition
 339 rates, such as 1000 Hz (Figure 3b). The ability to acquire data at such high frequencies
 340 is valuable for capturing rapid synaptic events and amplitudes with high temporal
 341 precision. However, high noise levels often complicate these high-frequency
 342 recordings, making it challenging to identify true responses amidst false-positive
 343 threshold crossings (Figure 3b, top). The denoised recording, on the other hand, has
 344 a considerably improved signal-to-noise ratio (Figure 3b, bottom), like the improvement
 345 observed in previous recordings at 100 Hz. Therefore, Neuroimage Denoiser can
 346 facilitate the analysis of recordings acquired at very high frequencies without the need
 347 to re-train a new model. Acquiring at these high rates opens the door to various

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under a [CC-BY-NC 4.0 International license](#).

348 applications, such as analyzing multi-vesicular or asynchronous releases from a single
349 synapse, which would yield variable amplitudes and subsequent peaks, or resolving
350 the precise time from stimulus to glutamate release with higher temporal resolution.
351 Additionally, it enables the study of rapid synaptic plasticity mechanisms and the
352 precise kinetics of neurotransmitter release and clearance. The camera-based imaging
353 will allow the comparison of direct multiple synapses in the field of view, which will
354 outcompete scanning microscopy-based approaches, where only single synapses can
355 be imaged at necessary high acquisition rates (>100 Hz).

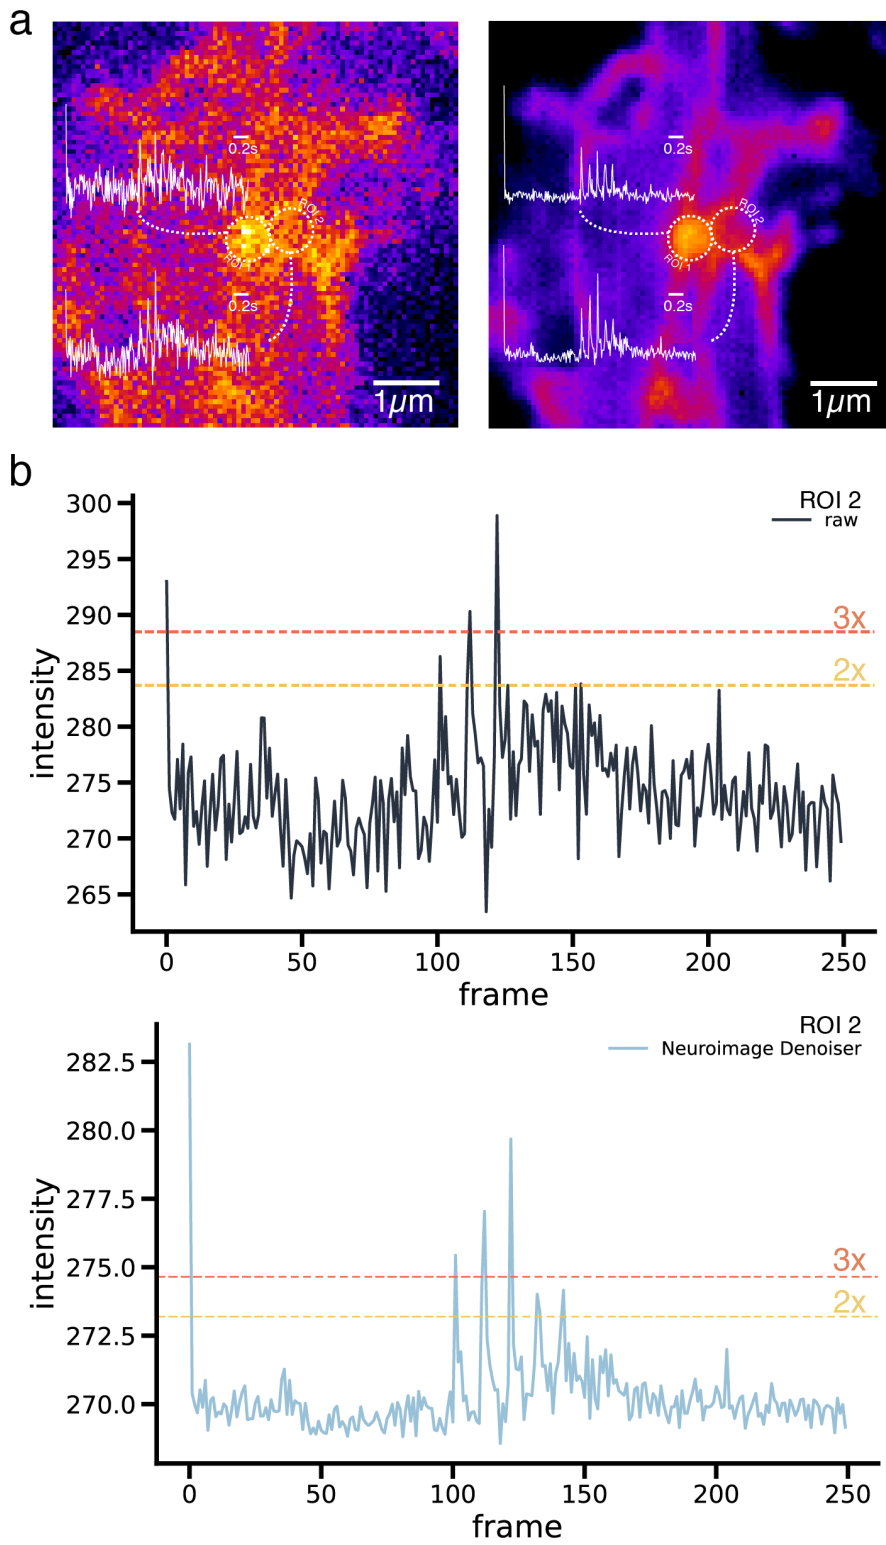

356

357 Application of Neuroimage Denoiser on alternative Glutamate Sensor to 358 study Synaptic Plasticity

359 Since Neuroimage Denoiser is not bound to a certain sensor and its associated kinetics
360 but only to its localization, we applied the denoising to recordings of fast
361 iGluSnFR.S72A¹³. This version of the sensor has faster kinetics, but a lower signal-to-
362 noise ratio compared to iGluSnFR3.v857.SGZ¹¹ particularly due to the high noise level
363 present in the baseline of the recording (until stimulation at frame 100). This noise in
364 the baseline elevates the threshold above which a signal is considered a release event.
365 iGluSnFR.S72A¹³ is useful for plasticity studies since the kinetic properties allow the
366 recording of synaptic release events up to 20 Hz pulse interval. Conventionally such
367 recordings are done via patch-clamp¹³, which will not allow reaching the single synapse
368 resolution as easily as imaging approaches. Conversely, iGluSnFRs timing and
369 localization of excitatory synaptic inputs⁸ enable a more complete picture of the
370 synaptic plasticity of a neuron under a given condition, which is of particular interest
371 for investigating the molecular mechanisms underlying synaptic plasticity. Key
372 plasticity metrics are the paired-pulse ratio, quantifying facilitation or depression of
373 consecutive responses, and the failure rate, measuring the proportion of stimuli failing
374 to evoke a response hence indicating release probability. Nevertheless, due to the low
375 signal-to-noise level and the fast bleaching of the sensor, the recordings are
376 superimposed by noise (Figure 4a, left) that considerably complicates the identification
377 of responding synapses and to differentiate between response and failure within the
378 average trace of a selected synapse (Figure 4b, top). The given example in Fig. 4
379 illustrates the impact of noise in fast pulse trains. Even though a very small threshold
380 multiplier of two is applied to the raw average trace the responses to the stimulus given
381 at frames 130 and 140 are not detected. Moreover, the noise in the raw data (Figure
382 4b, top) obscures these responses, while the denoised trace (Figure 4b, bottom)
383 reveals clear and distinct responses upon each of the five stimuli. Thus, the failure rate
384 can be determined to be 0% after applying denoising with Neuroimage Denoiser
385 (threshold multiplier 2), contrary to 40% in the raw trace (threshold multiplier 2).
386 Additionally, when computed with a multiplier of two (yellow dashed line, Figure 4b),
387 the low threshold leads to the detection of false positive responses in the raw trace.

397 *threshold multipliers is indicated as yellow and orange dashed lines, for multipliers two and three respectively.*

398 Discussion

399 In this manuscript, we presented Neuroimage Denoiser – a U-Net-based²⁰ deep-
400 learning framework to reduce noise levels in microscopic imaging recordings. By
401 incorporating the concepts of Noise2Noise²⁷, the Neuroimage Denoiser framework is
402 highly flexible for a wide array of experimental settings and does not require re-training
403 for changed parameters. In the past, researchers developed several sensors to study
404 functional neurobiology for the dynamics of calcium²⁸, GABA²⁹, dopamine³⁰,
405 acetylcholine³¹, and glutamate^{11,29} on a single synapse level. These recordings are
406 superimposed with noise regardless of the sensor and acquisition rate. Consequently,
407 a unified model capable of denoising recordings when having the same localization
408 would considerably ease the downstream processing. Therefore, we tested our model
409 by applying the denoising routine to changed parameters, i.e. recording frequency
410 (Figure 3) and sensor (Figure 4), and obtained convincing results. The proposed
411 framework is capable of considerably reducing the noise in experiments with fast
412 dynamics, as typical for glutamate imaging, which did lead to artifacts in responses
413 when using previously described deep learning frameworks³ (Supplementary Figure
414 1). One of the advantages of Neuroimage Denoiser is its ability to preserve the
415 amplitude of synaptic responses, as evidenced by a high correlation ($R = 0.9966$, $p <$
416 0.0001) between denoised and raw responses (Figure 2c). Further, the improved
417 signal-to-noise level helps to resolve complex synapses spatially (Figure 3) which can
418 ease the analysis of spontaneous activity and be used as a functional readout for
419 molecular manipulation to define release mechanisms in specific synapses.

420 We anticipate that Neuroimage Denoiser can be adopted in many laboratories as it
421 has minimal hardware requirements, and the preparation of the training data is
422 automatically balanced for optimal results. The framework is easy to use for data
423 preparation, training, grid search, and inference (denoising) and does not require
424 additional programming knowledge, making it accessible to a broad range of
425 researchers in the field of neuroscience. Although glutamate imaging as a neural
426 recording method can provide rich and diverse datasets, these data have a high
427 complexity with many disruptive elements, such as noise, bright sensor depositions, or
428 vesicular transport of sensor, that make the creation of ground truth data for training a
429 model on responding regions of a recording challenging. Our training data preparation
430 routine offers a way to balance the training data without time-consuming manual
431 intervention and curation. We tested a several potential training parameters (Table 1)

bioRxiv preprint doi: <https://doi.org/10.1101/2024.06.08.598061>; this version posted June 10, 2024. 432 to select the most performant parameter combination, however, users can freely
433 choose a combination suited for their experimental set-up and analysis.
434 Neuroimage Denoiser is anticipated as a framework for fast responses and is
435 specifically trained to denoise glutamate imaging recordings. However, its flexibility
436 ensures that it is well-suited to work for a variety of typical functional experiments to
437 improve the signal-to-noise ratio.

Supplementary Figure 1 a) Schematic representation of a U-Net in the style of DeepInterpolation. Predictions are made based on five frames before and after the target frame (which is omitted). The model predicts tries to predict the omitted frame. b) Example of an artifact produced by a DeepInterpolation-styled approach (orange) to denoising for the fast kinetic of iGluSnFR. The peak is not preserved, instead, a double peak emerges with the original peak being of lower intensity than the preceding and succeeding frames. c) Raw, DeepInterpolation, and Neuroimage Denoiser denoised recordings of the synapse. Stimulation was applied at frame 20. It is visible that DeepInterpolation shifts the peak response from frame 21 to frame 22.

3 Overall discussion and conclusion

The development of the neuronal networks within the cerebral cortex is a remarkably complex process requiring precise temporal, cell-type-specific, and spatial regulation of gene expression, posttranscriptional RNA processing, and protein diversity. Dysregulation of these mechanisms involving critical neurodevelopmental genes has been consistently linked with the pathogenesis of various neurodevelopmental disorders, such as autism spectrum disorder, epilepsy, and schizophrenia. For instance, misexpression, splicing, or mutations in the Reelin gene, essential for guiding neuronal migration, have been causally associated with these conditions^{127–129}. While genetic mutations can disrupt gene expression, posttranscriptional RNA processing, and the resulting proteomic landscape, various regulatory mechanisms also play a crucial role in shaping gene expression and protein isoform composition during cortical development. This thesis explored these complex regulatory mechanisms through five interconnected studies, focusing on miRNA regulation and alternative splicing in cortical development. Key findings include the identification of crucial RNA-binding protein interactions, comprehensive miRNA expression profiling across key embryonic developmental stages, the implementation of a novel bioinformatics resource, and insights into cell type-specific alternative splicing of voltage-gated calcium channels.

The overarching aim of this thesis was to elucidate the critical roles of posttranscriptional regulatory mechanisms, specifically involving microRNAs and alternative splicing, in shaping the complex processes of cortical development. Across the five studies presented, several key findings emerged that collectively address this central research question. First, the regulation of RNA-binding proteins that guide the alternative splicing machinery was investigated. Here, this thesis focuses on RBFOX2 and elucidating its role during cortical development. Premature overexpression at an NPC-dominated stage of embryonic brain development disrupted the sensitive splicing balance and revealed an antagonistic relationship between RBFOX2 and PTBP2. Consequently, neuronal progenitor cells of the cerebral cortex failed to differentiate and migrate properly (**Figure 11**), highlighting the necessity for RNA-binding proteins to exhibit precisely timed and localized expression patterns. In this context, we demonstrated that the NPC-specific miR-92a-3p suppresses *Rbfox2* expression *in vivo*. Second, miRNA sequencing at distinct developmental stages of the cerebral

cortex (E14, E17, P0), as well as cell-specifically in NPCs/neurons, revealed changes in expression patterns throughout neuronal differentiation. The silencing effect was enhanced by the co-expression and cooperative binding of miRNAs to shared target mRNAs. Third, the web portal cortexa was developed to comprehensively analyze gene expression and alternative splicing dynamics across different developmental stages (E14 - 21 months) and cell types in the murine brain. Fourth, differences in alternative splicing patterns of voltage-gated calcium channels between neuronal cell types were studied. Alternative splicing events in the C-terminal region of VGCCs can regulate their coupling to scaffolding proteins, G-protein signaling, synaptic targeting, and, ultimately, synaptic transmission and plasticity across distinct neuronal populations. An impact on C-terminal splicing to channel gating and kinetics is shown in heterologous expression systems but must be confirmed in neurons. Finally, to bridge molecular mechanisms with functional outcomes, Neuroimage Denoiser, a deep-learning framework for removing noise from fluorescent signals in functional imaging and, therefore, considerably improving the quality of the recordings, was developed.

Figure 11 Illustration depicting the effects of *Rbfox2* overexpression on cerebral cortex development. **a** normal development, showing the typical layered structure from the ventricular zone (VZ) at the bottom to the cortical plate (CP) at the top. Neural progenitor cells (NPCs) in the VZ give rise to radial glial cells that span the

developing cortex. Intermediate progenitor cells in the subventricular and intermediate zones (SVZ/IZ) produce neurons that migrate along radial glia to form the cortical layers. **b** Alterations caused by *Rbfox2* overexpression, leading to a reduction in neurons reaching the cortical plate (migration defect) and an increase in NPC and intermediate progenitor cells in the SVZ/IZ (differentiation defect).

Many regulatory mechanisms are often described as binary events, i.e., alternative splicing “switches”^{8,21,130}, miRNA “suppression” or “silencing.” However, these processes usually involve more nuanced changes. For instance, miRNAs often fine-tune gene expression rather than completely silence their targets, thereby allowing for precise regulation of protein levels that can adapt to varying cellular conditions, and co-targeting offers yet another mechanism to modulate the magnitude of the silencing effect^{47,85}. Similarly, alternative splicing can result in subtle shifts in isoform ratios rather than absolute switches, generating protein diversity crucial for specialized cellular functions. This thesis demonstrated that one of these fine-grained transitions in alternative splicing was moderated by a network of factors, including PTBP1, PTBP2, RBFOX2, miR-92a-3p, and miR-124-3p. PTBP1, a strong exon repressor, induces nonsense-mediated decay of PTBP2, ensuring a mutually exclusive expression of these two members of the PTBP family. Conversely, PTBP2 acts as a weaker exon repressor, allowing for more nuanced splicing regulation. RBFOX2 antagonistically regulates exons also targeted by PTBP, adding another layer of control. miR-124-3p, by repressing *Ptbp1* expression, promotes neuronal differentiation, while miR-92a-3p represses *Rbfox2* and is highly expressed in neural progenitor cells and at early development stages. This multifaceted regulatory network ensures a gradual change from exon skipping to inclusion in neurodevelopmentally-relevant target genes. Furthermore, the role of RBFOX2 in the maturation of miRNAs and the ability of miR-92a-3p to silence *Rbfox2* adds another layer of complexity to this regulatory system³⁸.

To further unravel the intricate miRNA-mediated and alternative splicing regulatory mechanisms underlying cortical development, our studies provided two valuable resources. On one hand, our comprehensive miRNA sequencing data span key developmental time points (E14, E17, P0), NPCs, and *in vitro* differentiated neurons in the murine cerebral cortex. This dataset offers insights into the expression patterns of miRNAs throughout neuronal differentiation and migration. On the other hand, the

cortexa web portal is a powerful bioinformatics resource for in-depth analysis of gene expression and alternative splicing dynamics across an extensive developmental timeline (E14 to 21 months) and diverse cell types in the murine brain. Taken together, these findings provide a valuable starting point for future research on posttranscriptional regulation in the developing and adult mammalian brain.

While transcriptomic analysis can provide crucial hypotheses for molecular mechanisms of cortical development, the changes induced by such mechanisms on the function of neurons must be experimentally validated. Here, functional imaging of neurotransmitters or secondary messengers is a valuable tool to observe the real-time consequences of these regulatory processes. However, the subtle changes in neuronal function resulting from posttranscriptional regulation can be challenging to detect and analyze because the small signal amplitudes are superimposed with noise. To facilitate functional imaging specifically in the case of minor changes due to posttranscriptional regulation, I developed Neuroimage Denoiser, a deep-learning framework designed to remove noise from transient fluorescent signals in functional imaging, particularly in glutamate imaging. This tool significantly improves the signal-to-noise ratio while preserving signal amplitudes, enabling more accurate detection and localization of synaptic responses. The preservation of the amplitude is important because subsequent measures such as the paired-pulse ratio or quantal content are dependent on unaltered amplitudes. By enhancing the ability to study complex synaptic structures, spontaneous activity, and synaptic plasticity at high temporal and spatial resolutions, Neuroimage Denoiser offers a way to bridge molecular-level regulation and functional outcomes in neuronal communication and development. The enhanced signal localization achieved through Neuroimage Denoiser, combined with precise particle localization using ThunderSTORM (ImageJ), enables a more detailed examination of how alternative splicing of calcium channels influences the spatial organization of active zones, providing novel insights into synaptic structure-function relationships (Amaral et al., in preparation).

While our research has focused on specific posttranscriptional regulatory mechanisms and their role in shaping cortical development, the broader context of neuronal classification and function is also an interesting aspect to consider. The complexity we have observed in miRNA regulation⁴⁷ and alternative splicing^{37,38,131} suggests that

traditional methods of categorizing neuronal cell types may not fully capture the functional diversity present in the cerebral cortex. Traditionally, the classification of cell types is mostly performed on marker proteins, localization, and morphology for broad classification¹³². Using this approach, several proteins have been identified that can be used as markers for relatively specific cell types, e.g., VIP, CamKII, or PV^{23,78}. Associated with these cell types, specific promoters have been described that allow researchers to specifically express constructs of interest in these cells^{133,134}. Next-generation sequencing has been used to obtain the transcriptomes of these cell types by expressing a fluorescent marker under such a promoter and subsequently sorting these cells via fluorescence-activated cell sorting (FACS)^{23,135,136}. With the rise of single-cell sequencing methods, the classification of cell types within the mammalian brain has attracted increasing interest. In one such approach, individual cells are encapsulated into droplets, and the adapter sequences contain a unique barcode for each cell. Thus, the expression of genes can be characterized at single-cell resolution, and a more complex analysis and classification of cells can be performed¹³⁷. The Allen Brain Consortium conducted such an experiment on the neocortex and hippocampal formation and identified 388 transcriptomic types, including 364 neuronal types¹². Remarkably, they identified inhibitory neurons that showed differing morphological and connectional patterns. However, since they share a transcriptomic profile, the correspondence between these cell clusters could be established¹². Although the Allen Brain Consortium's transcriptomic atlas represents a significant advancement, it is important to recognize its limitations. The classification is primarily based on countable mRNA transcripts, which do not fully capture the true proteomic landscape of the cell. Several posttranscriptional mechanisms play crucial roles in shaping cellular function and identity, including alternative splicing, RNA modifications (such as m6A methylation), protein localization, protein-protein interactions, and posttranslational modifications. Moreover, translational efficiency, protein stability, and degradation rates all contribute to the final protein abundance and activity. These factors can lead to significant divergences between transcript levels and functional protein outcomes.

Furthermore, the Allen Brain Classification is based on a snapshot of gene expression in adult animals (P53 - P121)¹². The mammalian brain undergoes dynamic changes throughout development and even in its mature state. This single timepoint approach fails to capture the temporal dynamics of gene expression and cell type identity, which

are known to evolve substantially over time. Cells that appear transcriptionally distinct at one stage might converge functionally at another or vice versa¹³⁸.

The complexity of cortical cell types likely extends beyond what is currently revealed by standard transcriptomics. The functional diversity of neurons and glia in the cortex is influenced by a multitude of factors, including their developmental history, local environment¹³⁹, and activity-dependent changes¹⁴⁰. While these aspects are reflected in the transcriptome¹⁴¹, current methods may not fully capture this information. A more complete transcriptomic picture reflecting the true functional differences among cells could be obtained by considering RNA modifications, splicing variants, and other posttranscriptional events. This evolving understanding of neuronal classification underscores the importance of posttranscriptional regulation in shaping cellular identity and function. The subtle changes in gene expression and protein isoforms that can be observed through miRNA regulation and alternative splicing likely contribute significantly to the functional diversity of neurons, even when their overall transcriptomic profiles are similar.

The nuanced understanding of transcriptomic complexity we have gained through our research is not merely an academic pursuit but also has significant clinical implications. While traditional clinical approaches often focus on genetic mutations identified by whole exome sequencing (WES) as the primary source of pathology, mounting evidence suggests that aberrations in posttranscriptional processes, particularly mis-splicing and miRNA dysregulation, play a crucial role in various neurological and psychiatric conditions and diseases¹⁴².

For instance, splicing dysregulation has been linked to autism spectrum disorder^{143,144}, epilepsy^{32,145–147}, schizophrenia^{148–151}, cardiac hypertrophy^{61,152}, cancer^{153–156}, and other conditions and disorders¹⁵⁷. Similarly, miRNA dysregulation has been implicated in cancer¹⁵⁸, cardiovascular diseases¹⁵⁹, and neurodevelopmental or neurodegenerative diseases^{160,161}. Despite their significant impact on cellular processes and potential as biomarkers¹⁶² and therapeutic targets¹⁶³, current diagnostic and treatment approaches typically neglect these posttranscriptional mechanisms¹⁶⁴. Importantly, a considerable proportion (65-75 %) of rare diseases remain undiagnosed by traditional methods such as whole exome sequencing, microarrays, and gene

panels¹⁶⁴. This gap in diagnosis highlights the potential importance of considering posttranscriptional regulatory processes in disease etiology and treatment.

In addition to miRNA regulation and alternative splicing, other posttranscriptional processes are attracting increasing interest in the fields of neurodevelopment and disease. RNA modifications are emerging as a crucial layer of gene regulation that may have significant implications for cortical development and neurological disorders. There are more than 100 known chemical RNA modifications that are significantly dysregulated in human cancers¹⁶⁵. The most prevalent modification is N6-methyladenosine¹⁶⁶, which is applied to the 3'-UTR, 5'-UTR, untranslated intronic regions, and exonic regions¹⁶⁷. Adenosine is methylated within the consensus motif of DRACH³, and although this sequence is highly abundant, m⁶A modification is highly selective¹⁶⁷. The m⁶A reader protein YTHDC1 interacts with two RBPs that antagonistically regulate alternative splicing events, SRSF3 and SRSF10. Interestingly, m⁶A modification and subsequent YTHDC1 binding promotes the binding of SRSF3 while decreasing the affinity of SRSF10¹⁶⁸, thereby enabling splicing regulation through RNA modifications. RNA modifications may also affect splicing outcomes directly by altering the binding affinity of RNA-binding proteins to RNA or changing the accessibility of the binding sites through altered RNA structure¹⁶⁹. Pseudouridine, another RNA modification, is specifically enriched in the binding sites of many RBPs (e.g., U2AF2, KHSRP, and PTBP1). Furthermore, the knockout of pseudouridine synthases was linked to aberrant changes in the alternative splicing landscape¹⁷⁰. Interestingly, pseudouridine was enriched (z score = 4.107) in the reported eCLIP peaks, while unmodified uridine was underrepresented for RBFOX2 (z score = -16.705). Thus, pseudouridine potentially modulates many RBP-RNA interactions, suggesting that this modification may also influence the binding preferences of RBFOX2 and subsequent splicing regulation. Although these first results imply a broad influence of RNA modifications on mRNA posttranscriptional processing and specifically on alternative splicing, many RNA modifications and their implications for alternative splicing have not yet been studied.

³ R = purine, H = A, C, or U

In conclusion, this thesis revealed a complex landscape of posttranscriptional regulation, specifically focusing on miRNA regulation and alternative splicing during cortical development. This work, along with emerging research on RNA modifications and other regulatory mechanisms, underscores the need for a more comprehensive approach to understanding gene expression in the developing brain. Future research should aim to integrate these various layers of posttranscriptional regulation to build a more complete picture of how the remarkable complexity of the mammalian brain is achieved.

4 Outlook

The findings presented in this thesis contribute to our understanding of the complex landscape of posttranscriptional regulation in cortical development. As research is conducted to understand the intertwined regulation between miRNA regulation, alternative splicing, and emerging mechanisms such as RNA modifications, several key areas for future research appear. Moving forward, a primary focus should be integrating these various regulatory mechanisms to provide a more comprehensive view of posttranscriptional control. By combining data on miRNA regulation, alternative splicing, and RNA modifications, a more holistic understanding of how these processes collectively shape gene expression and protein diversity in the developing cortex can be reached.

The rise of single-cell methods has significantly advanced our understanding of gene expression within the central nervous system, with landmark studies conducted by the Allen Brain Institute leading to the classification of hundreds of transcriptomic cell types^{12,171–173}. Recent studies have gradually shifted to focusing on epigenetic features at single-cell resolution in different compartments of the mammalian brain^{174–177}, with some resolving spatial resolution even for different nuclear compartments¹⁷⁸. However, these assays often combine transcriptomics with a chromatin accessibility approach due to technical limitations of second-generation sequencing approaches (e.g., sequencing by synthesis as employed by the widely used Illumina systems) and do not allow for alternative splicing analysis, as they typically capture only the 3' end of transcripts. Thus, current approaches do not capture several posttranscriptional regulatory layers, i.e., miRNA regulation, alternative splicing, and RNA modifications. The rise of novel third-generation nanopore sequencing approaches paves the way for more comprehensive single-cell multi-omics analyses. These technologies offer the potential to sequence direct RNA with full-length transcripts, enabling the detection of alternative splicing events and RNA modifications at single-cell resolution. This advancement will lead to a deeper understanding of cellular heterogeneity and regulatory mechanisms, integrating multiple layers of gene regulation in individual cells of the brain.

Future research could explore how aberrations in posttranscriptional processes contribute to various neurological and psychiatric conditions. Given the limitations of

current diagnostic methods, investigating miRNA dysregulation, mis-splicing, and RNA modifications and their combinations could provide new insights into the etiology of rare and undiagnosed diseases. This line of research may also uncover novel biomarkers and therapeutic targets for conditions such as autism spectrum disorder, epilepsy, and schizophrenia, making recent developments in real-time sequencing highly relevant^{179–181}.

Building on our findings, future studies should aim to capture the temporal dynamics of posttranscriptional regulation throughout development and into adulthood at the single-cell level. This approach could reveal how regulatory networks evolve over time and contribute to different neuronal populations' functional maturation. Longitudinal studies combining transcriptomics, alternative splicing analysis, and miRNA profiling could provide a more nuanced understanding of brain development and cellular plasticity.

In conclusion, significant advancements have been made in the field of posttranscriptional regulation of gene expression. By integrating multiple regulatory layers and leveraging single-cell total RNA sequencing with nanopore technology, future research has the potential to broaden our understanding of brain development and function.

6 Appendix

6.1 Contribution to individual publications

Table 1 Contributor role according to CRediT Taxonomy: an overview of the contributions to case studies 1-5.

	1	2	3	4	5
Scientific publication	Premature upregulation of miR-92a' s target RBFOX2 hijacks PTBP splicing and impairs cortical neuronal differentiation.	Stage-specific expression patterns and cotargeting relationships among miRNAs in the developing mouse cerebral cortex.	Cortexa: a comprehensive resource for studying gene expression and alternative splicing in the murine brain.	More than a pore: How voltage-gated calcium channels act on different levels of neuronal communication regulation	Neuroimage Denoiser - a Deep Learning Framework for Removing Noise from Transient Fluorescent Signals in Functional Imaging.
Conceptualization Ideas, formulation or evolution of overarching research goals and aims	40 %	20 %	100 %	10 %	100 %
Methodology Development or design of methodology; creation of models	50 %	40 %	100 %	40 %	100 %
Software Programming, software development; designing computer programs; implementation of the computer code and supporting algorithms; testing of existing code components	90 %	30 %	50 %	100 %	95 %
Validation Verification, whether as a part of the activity or separate, of the overall replication, reproducibility of results, or experiments and other research outputs	30 %	20 %	100 %	0 %	100 %

Formal analysis Application of statistical, mathematical, computational, or other formal techniques to analyze or synthesize study data	80 %	40 %	100 %	100 %	100 %
Investigation Conducting a research and investigation process, specifically performing the experiments, or data/evidence collection	20 %	20 %	100 %	10 %	50 %
Resources Provision of study materials, reagents, materials, patients, laboratory samples, animals, instrumentation, computing resources, or other analysis tools	0 %	0 %	0 %	0 %	0 %
Data Curation Management activities to annotate (produce metadata), scrub data and maintain research data (including software code, where it is necessary for interpreting the data itself) for initial use and later reuse	80 %	40 %	100 %	100 %	100 %
Writing – Original Draft Preparation, creation and/or presentation of the published work, specifically writing the initial draft (including substantive translation)	80 %	40 %	100 %	10 %	100 %
Writing – Review & Editing Preparation, creation and/or presentation of the published work by those from the original research group, specifically critical review, commentary or revision including pre or post publication stages	20 %	60 %	30 %	20 %	30 %
