geboren am 04.08.1993 in Zagreb, Kroatien

JOHANNES GUTENBERG  
UNIVERSITÄT MAINZ

Mainz, 15. Juli 2024

**Dekan:** Prof. Dr. Eckhard Thines

**1. Berichterstatter:** Redacted

**2. Berichterstatter:** Redacted

**Tag der mündlichen Prüfung:** 21.08.2024

## **Declaration**

I, Ivan Mikicic, confirm that the work presented in this thesis is my own. Where information has been derived from other sources, I confirm that it has been indicated in the thesis. Throughout the thesis I have received support regarding experimental design by my supervisor. I have also received experimental support from the colleagues in the lab, some of whom I have supervised for their thesis research. Western blot in the Figure 5B, as well as the optimization of the bioinformatics workflows for phosphoproteomics analysis were performed by redacted. Data for the following figures were contributed by redacted: Figure 7C,D,E; Figure 9B,C,D,E,F; Figure 12G. Data for the Figure 8G were provided by redacted. The Western blot experiment for the Figure 12H,I was performed by redacted.

## Abstract

R-loops, structures consisting of an RNA:DNA hybrid and a displaced DNA strand, are increasingly investigated as a cell-intrinsic and cancer-relevant source of replication stress (RS). On the other hand, RS stabilizes R-loops in actively replicating and transcribing regions. This suggests potential unexplored mechanisms through which cells mitigate toxic accumulation of RS-borne R-loops.

To investigate the relationship between the replication stress and R-loops, we first stratified RS by severity in HCT116 cells, reasoning that mild RS might have a distinct signaling signature in comparison to moderate or strong RS. Next, we employed multiplexed mass spectrometry-based phosphoproteomics to investigate the regulation of R-loop resolving enzymes upon induction of different levels of RS. Comparisons of aphidicolin- and oncogene-induced RS revealed similarities at the phosphoproteome level, and a common loss of phosphorylation on RNA processing factors. Interestingly, we found that RS reduces phosphorylation of a major R-loop nuclease, RNase H1, at three residues (S74, S86 and S80) adjacent to its hybrid-binding domain.

The kinase search revealed that DYRK1A phosphorylates RNase H1 at S74. Phosphoproteomics analyses revealed that the reduction in DYRK1A signaling is a driver of RS-mediated loss of phosphorylation on RNA processing factors. Finally, we explored functions of RNase H1 phosphorylation. In *in vitro* assays, the triple phospho-mimicking (S3xD) mutant of RNase H1 had decreased binding to RNA:DNA hybrids in comparison to wild-type or phospho-dead (S3xA) mutant, implying that phosphorylation directly impacts binding to hybrids. In cells, the S3xD mutant showed decreased separation between nucleoli and the nucleoplasm in comparison to S3xA. Finally, interactome analyses with the phospho-mutants and after DYRK1A inhibition revealed phosphorylation-based interactors of RNase H1 and implicated GSK3 $\beta$  in the regulation of RNase H1 stability.

In summary, this work presents major advancements in the understanding of DYRK1A signaling, and of the regulation of activity and stability of RNase H1 by phosphorylation. This could impact the use of RNase H1 as a tool in R-loop biology and advance the understanding of DYRK1A function in disease.

## Zusammenfassung

R-Loops, Strukturen bestehend aus einem RNA:DNA-Hybrid und einem verdrängten DNA-Strang, werden zunehmend als zellintrinsische und krebsrelevante Quelle von Replikationsstress (RS) untersucht. Andererseits stabilisiert RS die R-Loops in aktiv replizierenden und transkribierenden Regionen. Dies deutet auf potenzielle unerforschte Mechanismen hin, durch die Zellen die toxische Akkumulation von RS-bedingten R-Loops abmildern.

Um die Beziehung zwischen Replikationsstress und R-Loops zu untersuchen, haben wir zunächst RS nach Schweregrad in HCT116-Zellen klassifiziert, mit der Überlegung, dass milder RS im Vergleich zu moderatem oder starkem RS eine distinkte Signalsignatur haben könnte. Anschließend setzten wir multiplexe, massenspektrometrie-basierte Phosphoproteomik ein, um die Regulation von R-Loop-auflösenden Enzymen bei Induktion verschiedener RS-Level zu untersuchen. Vergleiche von Aphidicolin- und Onkogen-induziertem RS zeigten Ähnlichkeiten auf Ebene der Phosphoproteomik und einen gemeinsamen Verlust der Phosphorylierung von Faktoren der RNA-Prozessierung. Interessanterweise stellten wir fest, dass RS die Phosphorylierung einer wichtigen R-Loop-Nuklease, RNase H1, an drei Resten (S74, S86 und S80), welche an die Hybrid-Bindungsdomäne angrenzen, reduziert.

Die Kinase-Suche ergab, dass DYRK1A RNase H1 an S74 phosphoryliert. Phosphoproteomik-Analysen zeigten, dass die Reduktion des DYRK1A-Signalwegs eine Triebkraft des RS-vermittelten Verlustes der Phosphorylierung von Faktoren der RNA-Prozessierung ist. Schließlich untersuchten wir die Funktionen der Phosphorylierung von RNase H1. In *in-vitro*-Assays zeigte die dreifach Phosphorylierung-imitierende (S3xD) Mutante von RNase H1 eine verringerte Bindung an RNA:DNA-Hybride im Vergleich zum Wildtyp oder zur nicht-phosphorylierbaren (S3xA) Mutante. Dies deutet darauf hin, dass die Phosphorylierung die Bindung an Hybride direkt beeinflusst. In Zellen zeigte die S3xD-Mutante eine verringerte Trennung zwischen Nukleoli und Nukleoplasma im Vergleich zur S3xA-Mutante. Schließlich deckten Interaktom-Analysen mit den Phosphorylierungs-Mutanten und nach Hemmung von DYRK1A phosphorylierungsbasierte Interaktoren von RNase H1 auf und implizierten GSK3 $\beta$  in der Regulation der Stabilität von RNase H1.

Zusammenfassend präsentiert diese Arbeit bedeutende Fortschritte im Verständnis des DYRK1A-Signalwegs und der Regulation der Aktivität und Stabilität von RNase H1 durch Phosphorylierung. Dies könnte die Verwendung von RNase H1 als Werkzeug in der R-Loop-Biologie beeinflussen und das Verständnis der DYRK1A-Funktion bei Krankheiten vorantreiben.

# Chapter 1

---

## Introduction

---

### **1.1. Post-translational modifications as the backbone of cellular signalling**

While genes are information storage of the cells, proteins are the main workers, engaging with each other and other components of the cell and catalyzing biochemical reactions to achieve DNA replication, transcription, RNA processing and modification, translation of RNA into proteins, movement of organelles and cells, organization of cells and organelles, energy production and storage, cellular export and import, recycling of cell components, and many other activities. Whereas the human body contains only about 20,000 proteins, it needs to utilize them for a much larger number of discrete actions. To achieve this, proteins are chemically modified in a process called post-translational modification, vastly increasing their functionality. More than 400 posttranslational modifications (PTMs) have been reported, affecting all amino acid side chains, as well as protein termini<sup>1</sup>.

#### **1.1.1. Protein phosphorylation**

The best studied PTM is a small, reversible modification of polar amino acids called phosphorylation. It consists of a nucleophilic substitution, where a hydroxyl group of an amino acid side chain (serine, threonine or tyrosine) is replaced with a phosphate group using adenosine triphosphate (ATP) as the donor. The reaction is catalysed by enzymes called kinases and reversed by phosphatases. Serines are by far the most commonly modified amino acid, accounting for over 50% of all phosphorylation events<sup>2</sup>. At least two thirds of human proteins are known to be phosphorylated<sup>3</sup>, and the database PhosphoSitePlus reports around 230 000 unique human phosphorylation (phospho-) sites. Phosphorylation is a highly versatile modification, involved in majority of cellular processes, and affecting protein function in multiple ways. It can change protein localization, activity, stability, induce a conformation change or influence interactions of proteins with other molecules, including other proteins<sup>4</sup>.

#### 1.1.1.1. Protein kinases

The human proteome consists of around 550 protein kinases divided into over 50 families by evolutionary similarity<sup>5</sup>. Kinases differ by acceptor amino acid and substrate specificity. Broadly, they can be divided into serine-, threonine-, serine/threonine- and tyrosine-directed kinases. They commonly phosphorylate multiple substrates, with serine/threonine kinases having more than 200, and tyrosine kinases more than 1000 target phospho-sites on average<sup>6</sup>. Substrate specificity is commonly determined by a short patch of amino acids around the phosphorylated residue called a substrate motif or a phospho-motif. Phospho-motif averaging of all known substrates of a particular kinase produces a consensus motif, which helps to identify critical residues important for kinase specificity. Based on the substrate specificity, kinases can be divided into groups such as proline-directed (P at +1 position), basophilic (positively charged amino acids around, usually ahead of, the phospho-site), acidophilic (negatively charged amino acids around the phospho-site), glutamine-directed (Q at +1)<sup>7</sup> etc.

#### 1.1.1.2. Hierarchical phosphorylation

Phospho-sites are often spaced closely together, enabling coordinated phosphorylation by one or more kinases. Such events, where multiple closely spaced sites are phosphorylated in a defined order, are called hierarchical phosphorylation<sup>8</sup>. A well-studied example is the CK2 kinase, which can phosphorylate patches of multiple nearby serines interspersed with negatively charged amino acids, with crucial phosphoserines at +1 and +3<sup>8</sup>. Since CK2 is an acidophilic kinase, the negative charge introduced by the first phosphorylation event favors subsequent nearby modifications.

Multiple kinases can also cooperate in hierarchical phosphorylation. The initial event in such cases is called priming, and is performed by a priming kinase. Subsequent phosphorylation events are catalysed by a processive kinase<sup>9</sup>. This stepwise mechanism requiring multiple actors enables more elaborate regulation of the substrate function. For example, processes that inhibit the processive kinase but enable priming might lead to a different functional outcome (mono-phosphorylated substrate) than processes where both kinases are active (multi-phosphorylated substrate). On the other hand, by inhibiting the priming kinase, any phosphorylation of the substrate is turned off, without requiring regulation of the processive kinase.

Common priming kinases include DYRK1A and DYRK2, while GSK3 is a common processive kinase<sup>9</sup>. CK1 can act as both a priming and a processive kinase. For the purposes of this work, I will introduce DYRK1A as an example of a priming kinase, and GSK3B as a processive kinase, and expand on their functions and biology.

### 1.1.1.3. DYRK1A

DYRK1A is a member of the Dual-specificity tyrosine phosphorylation-regulated kinase (DYRK) family of serine/threonine kinases within the CMGC (containing CDK, MK, GSK and CDK-like members) kinase superfamily. The defining feature of this family, evident in their name, is their dual specificity – DYRK kinases are activated by autophosphorylation on tyrosine residues, but phosphorylate other substrates on serines and threonines<sup>10</sup>. In case of the human DYRK1A, the autophosphorylation occurs on the conserved tyrosine (Y321) within the activation loop<sup>11</sup>. DYRK1A shares a high domain similarity with other members of the family (DYRK1B, 2, 3 and 4), with DYRK1B being the most similar. Aside from domains shared with DYRK1B, DYRK1A contains two additional C-terminal features, a histidine repeat (H) and a serine/threonine repeat (S/T), with the former being required for its recruitment to RNA polymerase II (RNAPII) condensates<sup>12</sup>. Accordingly, DYRK1A phosphorylates RNAPII at its C-terminal domain (CTD), affecting transcriptional elongation<sup>13</sup>. Unlike the pTEF-b complex, which phosphorylates RNAPII genome-wide<sup>14</sup>, DYRK1A acts on RNAPII only at a subset of promoters containing a highly conserved palindromic DNA motif required for DYRK1A recruitment. The target genes transcriptionally regulated by DYRK1A are involved in translation, RNA processing and the cell cycle regulation<sup>13</sup>.

In line with having two nuclear localization signals (NLSs), DYRK1A localizes to the nucleus, but is also present in the cytoplasm<sup>15</sup>, suggesting a wide range of potential substrates. Aside from RNAPII, DYRK1A phosphorylates a variety of other substrates involved in transcription and signaling (DCAF7, NFAT, STAT3, TRAF3, FOXO1), tyrosine kinase regulation (c-met, SPRY2, EGFR), cell cycle regulation (LIN52, Cyclin D1 and D3, p27, CDC23), alternative splicing (SRSF1, SRSF2, SRSF6 and SF3B1) and DNA damage response (RNF169, SIRT1)<sup>10</sup>.

The *DYRK1A* gene is encoded on chromosome 21. Trisomy 21 (also known as the Down syndrome, or DS) is the most common autosomal aneuploidy among newborns<sup>16</sup>.

Accordingly, the *DYRK1A* gene is amplified in DS, giving rise to the overexpressed protein, including in the brain<sup>17</sup>. DS is characterized by intellectual impairment, early onset Alzheimer's disease, congenital heart disease, hypotonia, and other developmental problems<sup>18</sup>. Multiple studies point to a causative role of *DYRK1A* disbalance in neurological and neurodegenerative phenotypes of DS individuals<sup>19,20</sup>. Therefore, inhibition of *DYRK1A* is considered a promising therapeutic target to improve cognitive deficits in DS<sup>18</sup>.

Multiple roles have been described for *DYRK1A* in the cell cycle maintenance. It is necessary for assembly of the G0-maintaining DREAM complex through phosphorylation of its subunit LIN52, and therefore promotes quiescence and senescence<sup>21</sup>. Interestingly, the DREAM complex reduces somatic DNA repair capacity by repressing DNA repair genes, which can be rescued by inhibition of *DYRK1A*, with positive impacts on *C. elegans* aging. Furthermore, *DYRK1A* interacts with and phosphorylates the E3 ubiquitin ligase RNF169, enhancing its ability to recruit 53BP1 to sites of DNA double-strand breaks (DSBs). Additionally, *DYRK1A* is required for maintaining basal 53BP1 expression<sup>22</sup>. Since 53BP1 favors non-homologous end joining (NHEJ) over homologous recombination (HR), depletion of *DYRK1A* increases HR and resistance to DNA damage<sup>23</sup>. Altogether, this suggests that depletion or inhibition of *DYRK1A* has positive effects on genome stability maintenance.

#### 1.1.1.4. GSK3 $\beta$

The glycogen synthase kinase (GSK3) is an important factor in the insulin and Wnt signalling pathways. It has two isoforms, GSK3 $\alpha$  and GSK3 $\beta$ . GSK3 $\beta$  phosphorylates S/T residues which were primed at +4<sup>24</sup>. In some cases, negatively charged amino acids can mimic phosphorylation at +4, allowing for processive GSK3 $\beta$  activity<sup>25</sup>. GSK3 $\beta$  activity can be primed by different kinases: CK1, CDK5, PKA, ERK2, CK2 and the *DYRK* family<sup>26</sup> (see 1.1.1.5). There are multiple instances of sequential phosphorylation by GSK3 $\beta$ , at a series of serines or phospho-serine mimics separated by 4 residues, leading to hierarchical multisite phosphorylation<sup>27</sup>.

While functional consequences of GSK3 $\beta$  are varied, I will single out the role of GSK3 $\beta$  in protein degradation. Commonly, GSK3 $\beta$  introduces the so-called phospho-degron into substrates, allowing for ubiquitin-assisted proteasomal degradation<sup>26</sup>. There are at least

29 targets the stability of which is regulated by GSK3 $\beta$  and the proteasome<sup>26</sup>. Typically, the GSK3 $\beta$ -induced phospho-degron recruits the cullin-RING family E3 ubiquitin ligase complex called SCF<sup>28</sup>. Upon K48-linked ubiquitylation of the substrate, it is directed into proteasomal degradation. Among the best studied GSK3 $\beta$  phospho-degron substrates are MYC (T58)<sup>29</sup> and JUN (S251)<sup>30</sup>.

#### 1.1.1.5. Cooperation between DYRK1A and GSK3 $\beta$

A well-characterized example of the DYRK1A-GSK3 $\beta$  cooperation is the microtubule growth protein Tau. DYRK1A primes Tau, and processive phosphorylation is catalysed by GSK3 $\beta$ <sup>31</sup>. Overproduction of DYRK1A in DS results in more priming and increased hyperphosphorylation and aggregation of Tau, which is seen as a causative factor in early onset Alzheimer's disease, a common characteristic of DS<sup>19</sup>. Interestingly, the same study reports that phosphorylation of a translation initiation factor eIF2B $\epsilon$  is primed by DYRK1A and continued by GSK3 $\beta$ <sup>31</sup>. These two kinases also cooperate in phosphorylation of another microtubule growth factor, MAP1B. MAP1B regulates microtubule dynamics at growing axons and growth cones, and DYRK1A depletion compromises neuritogenesis and microtubule dynamics in cortical neurons, possibly by alterations in MAP1B phosphorylation<sup>32</sup>.

Interestingly, DS individuals have a reduced incidence of solid tumors<sup>33</sup>. This is likely a consequence of changes in phosphorylation of the transcription factor called nuclear factor of T cells (NFAT). DYRK1A primes NFAT in the nucleus for processive phosphorylation by GSK3 $\beta$  and CK1. Fully phosphorylated NFAT is exported from the nucleus to the cytoplasm, repressing the tumor angiogenesis transcriptional program<sup>34</sup>.

### 1.1.2. Protein ubiquitylation

Aside from small chemical groups (methyl, acetyl, phosphate) serving as PTMs, whole proteins can also be covalently attached to existing proteins. One of the best known examples is the 76 amino acid long, 8.6 kDa protein called ubiquitin, as well as a family of structurally related proteins, termed ubiquitin-like modifiers (including SUMO, NEDD8, UFM1, and others). Ubiquitin typically attaches to the  $\epsilon$ -amino group of substrate lysines using its C-terminal glycine. Aside from lysines, other amino acids can also get ubiquitylated, most prominently the N-terminal methionine<sup>35</sup>. A defining feature of ubiquitin

signaling is its modularity: ubiquitin not only attaches itself to a substrate, but can also get ubiquitylated itself, giving rise to polyubiquitin chains. Moreover, ubiquitin has multiple amino acids available for modification, enabling distinct topologies. Sequential ubiquitylation using one of the eight ubiquitin residues (M1, K6, K11, K27, K29, K33, K48 and K63) produces polyubiquitin chains of a particular linkage type (also called homotypic chains). Mixed (heterotypic) chains arise if a single chain contains at least two different linkage types. If a single ubiquitin within a chain gets modified on two distinct residues (eg. K63 and K48), it leads to chain branching. An additional consideration carrying potential functional information is the length of chains and branches. Considering the number of different branch types, as well as the fact that a substrate can get mono-, homo- or heterotypically poly- and branched polyubiquitylated at multiple acceptor amino acids, this enables a complex type of modification determining distinct functional outcomes, a phenomenon called the ubiquitin code.

#### 1.1.2.1. Enzymatic machinery for ubiquitylation

Ubiquitin is attached to target proteins through a series of enzymatic reactions involving ubiquitin-activating enzymes (E1), ubiquitin-conjugating enzymes (E2), and ubiquitin ligases (E3). E3 ligases carry out the final step of this process, covalent transfer of ubiquitin to a substrate, and are crucial for substrate selectivity<sup>36</sup>. The versatile nature of ubiquitin signaling is primarily realized through a large number of E3 enzymes, more than 600 of which have been described in humans. They are classified by domain identity into RING/U-box, HECT and RING-between-RING (RBR) E3 ligases. While HECT and RBR domains have intrinsic catalytic activity, RING and U-box domains function by facilitating the transfer of ubiquitin from the E2 enzyme to the substrate. Therefore, in contrast to HECT and RBR ligases, which themselves determine the linkage type, it is determined by the E2 enzymes in case of RING ligases. Removal of ubiquitin from substrates and disassembly of ubiquitin chains and branches are catalysed by specialized proteases called deubiquitinases (DUBs). Around 100 DUBs have been described in humans, and they are classified by the mode of catalysis into cysteine-based and zinc-binding metalloproteases. Based on selectivity, they can be classified into non-selective, chain type-selective, and chain type- and chain length type-selective DUBs<sup>37</sup>. A defining feature of DUBs is the presence of various ubiquitin-binding interfaces and domains, which help

to recognize and position ubiquitin chains for hydrolysis, enabling particular selectivity characteristics of each enzyme<sup>37</sup>.

#### 1.1.2.2. The ubiquitin-proteasome system (UPS)

Similarly to phosphorylation, ubiquitylation can serve a variety of functions, from changing a protein conformation, activity, interactions and localization to, most prominently, regulating protein stability. Canonically, degradation of proteins is induced by modification using the K48-linked ubiquitin chains. Recently, branched ubiquitin chains, typically containing K48 linkages, are being recognized as a widespread and high-efficiency degradation signal<sup>38</sup>. Degradation of ubiquitin-modified proteins is carried out by a large multi-subunit complex called the proteasome. It consists of two subcomplexes: the 20S core particle (CP) and the 19S regulatory particle (RP)<sup>39</sup>. The CP has a cylindrical structure composed of four stacked rings that facilitate entry of substrates into the cylinder and their proteolytic degradation. The inner ( $\beta$ ) rings of the CP contain the active sites with trypsin-like, chymotrypsin-like and caspase-like proteolytic activities. The RP is composed of a base and a lid, and caps one or both ends of the CP. It contains receptors recognizing 48-linked polyubiquitin chains, acting as the initial bridge between the substrate and the proteasome. Additionally, it contains AAA+ ATPase and other enzymatic activities necessary for substrate unfolding and translocation into the CP.

## 1.2. Replication stress

### 1.2.1. DNA replication

The coordinated steps each somatic cell undertakes before and during cell division is called the cell cycle, and can be divided into four distinct phases: G1, S, G2 and M. A defining feature of the cell cycle is its ability to precisely duplicate genetic information and equally divide it between the daughter cells during division. Genetic information is duplicated during DNA replication, taking place in S phase, with G1 phase serving to prepare cells for DNA replication. DNA origins, or origins of replication, are genomic loci from which DNA replication is initiated. In G1, they are bound by the Origin Recognition Complex (ORC), followed by recruitment of proteins CDC6 and CDT1, which are essential for loading of the double-hexameric helicase complex MCM2-7. The pre-Replication Complex (pre-RC) is formed upon loading of the inactive MCM2-7 complex, followed by phosphorylation-mediated activation driven by S-phase Cyclin-Dependent Kinases (S-

CDKs) and the Dbf4-dependent kinase (DDK, containing the catalytic subunit CDC7)<sup>40</sup>. Upon phosphorylation, additional components are recruited, including CDC45 and the GINS complex. This gives rise to the active replicative helicase termed the CMG (CDC45-MCM-GINS), and enables firing of the replication origins, a process in which the CMG helicase starts bidirectionally unwinding DNA molecules, enabling the replication machinery access to the DNA. Importantly, only a small subset of licensed replication origins are actually fired, the others remaining dormant and available for activation during S phase if required.

As DNA replication cannot be primed *ab novo* with DNA primers, it is initiated by the primase, a DNA-dependent RNA polymerase, which produces short RNA primers. Acting together with the primase, DNA polymerase  $\alpha$  then extends the RNA primers with short stretches of DNA. To enable continuous replication, a more processive complex is loaded, containing DNA polymerases  $\epsilon$  and  $\delta$ . Both strands of the DNA are duplicated simultaneously, but considering that replication takes place in the 5'-3' direction, synthesis of one strand (the leading strand) is continuous, whereas synthesis of the complementary strand (the lagging strand) is more complex and involves synthesis of stretches termed the Okazaki fragments (OFs). The OF synthesis requires repeated action of polymerase  $\alpha$ -primase and polymerase  $\delta$ . Active DNA synthesis takes place at the Y-shaped DNA region where the double-stranded parental DNA meets the nascent (newly replicated) DNA, called the replication fork (RF).

The multi-subunit complex containing DNA polymerases and other replication factors enabling replication of both the leading (polymerase  $\epsilon$ ) and the lagging strand (polymerase  $\delta$ ) is called the replisome. In addition to DNA polymerases, the replisome includes the processivity component called the sliding clamp (PCNA), clamp loader (RFC), the CMG helicase, the single-stranded binding factor Replication Protein A (RPA), topoisomerases relieving torsional stress, DNA ligases involved in sealing DNA nicks and factors involved in RNA primer removal and OF processing (RNase H, FEN1). As replication progresses, replisomes fired in opposite directions from adjacent origins move closer to each other. Once they converge, the CMG helicase is unloaded and disassembled, and DNA polymerases are released. To remove discontinuities in the newly replicated DNA, DNA overhangs (flaps) are removed by FEN1, and RNA primers are degraded by RNase H,

followed by gap filling and nick ligation. The replisome is highly flexible, and different components are recruited through protein-protein interactions (PPIs) depending on requirements of the particular replication step. Multiple mechanisms are employed to ensure fidelity and processivity of replication, as well as coordination between the leading and lagging strand synthesis.

### 1.2.2. Definition and sources of replication stress

Any stalling or slowing down of the replication fork is defined as the replication stress (RS)<sup>41</sup>. It derives from both endogenous (cellular or organismal) and exogenous (environmental) sources. Structural perturbations in DNA resulting from damaged DNA bases, mis-incorporated ribonucleotides, repetitive DNA sequences, secondary DNA structures such as G-quadruplexes or R-loops (see section 1.3) and transcription-replication conflicts (TRCs)<sup>42</sup> can impede with the progress of the fork and therefore lead to RS. Procedural sources involve depletion of deoxyribonucleotides (dNTPs) and an increase in origin firing rates<sup>43,44</sup>. The most common environmental sources of RS are UV irradiation, products of cellular metabolism such as reactive oxygen species (ROS) or aldehydes, and chemical mutagens and cytostatics. UV irradiation leads to formation of bulky DNA lesions such as thymidine dimers and 6,4-photoproducts, ROS induces oxidation of DNA bases, aldehydes trigger DNA inter-strand crosslinks and DNA-protein crosslinks, while other chemical mutagens cause a variety of chemical modifications of DNA. Hydroxyurea (HU) and aphidicolin (APH) are the most common RS-inducing cytostatics. Mechanistically, HU inhibits the ribonucleotide reductase, thereby depleting the dNTP pool. The tetracyclic diterpenoid APH is a natural product isolated from fungi such as *Cephalosporum aphidicola* and *Nigrospora oryzae* that directly inhibits replicative B-family DNA polymerases, including polymerases  $\alpha$ ,  $\delta$  and  $\epsilon$ <sup>45</sup>. HU and APH have been vital in studying the cellular response to RS, as they enable precise manipulation of treatment duration and dosage. In addition, owing to its anti-proliferative properties, HU has been used in the clinic for the treatment of clonal myeloproliferative disorders and solid tumors, although the treatment is associated with secondary leukemias as a result of mutagenicity and induction of chromosome instability<sup>46</sup>. Finally, replication stress is often induced by overexpression of oncogenes such as MYC, RAS or Cyclin E. In case of MYC and Cyclin E, RS is induced by premature S-phase entry while the G1 transcriptional

program is still taking place, leading to replication-transcription conflicts in highly transcribed genes<sup>47</sup>.

**Figure 1: Sources of replication stress.**

A number of different sources cause replication stress. This includes: damaged DNA bases; reactive oxygen species (ROS); mis-incorporated ribonucleotides; secondary DNA structures such as R-loops and G4s; inter-strand crosslinks; depletion of dNTPs by hydroxyurea; inhibition of DNA polymerases by aphidicolin; or transcription-replication conflicts, caused by elevated oncogene levels. RNR = ribonucleotide reductase.

### 1.2.3. Replication stress signaling

A defining attribute of RS is the fork-adjacent exposure of single-stranded DNA (ssDNA) as a result of decoupling of the stalled DNA polymerases with the CMG helicase<sup>48</sup>. Being more sensitive to DNA damage and nuclease attacks<sup>49</sup>, such stretches are bound and protected by the replisome component RPA. In fact, RPA is essential for protection of stalled forks, as extensive exposure of single-stranded DNA leads to depletion of the RPA pool and fork breakage<sup>50</sup>. Stretches of RPA-coated ssDNA and ssDNA-dsDNA junctions recruit the Ataxia telangiectasia and Rad3 related (ATR) kinase, the canonical RS response kinase. ATR is activated through interaction with its partner ATRIP, as well as with either of two proteins containing ATR-activating domains<sup>51</sup>, TOPBP1<sup>52</sup> and ETAA1<sup>53,54</sup>. ATR belongs to a family of serine/threonine directed Phosphatidylinositol 3-kinase-related kinases (PIKKs), and as such targets proteins at the S/T-Q motif<sup>55</sup>. It targets a multitude of described nuclear substrates, with the most well-known being the checkpoint kinase CHK1. CHK1 helps to spread the ATR-driven phosphorylation signals away from replication forks and ssDNA, which leads to several functional consequences. CHK1 phosphorylates and inhibits the CDC25A and CDC25C phosphatases, which

normally remove the inhibitory phosphorylations on CDKs catalyzed by WEE1 and MYT1 kinases. By preventing CDC25-mediated dephosphorylation and activation of CDKs like CDK1, CHK1 activity stabilizes the inhibitory phosphorylation state of CDKs, thereby inducing the cell cycle arrest. Aside from this, the ATR-CHK1 signaling also suppresses origin firing, stabilizes the replication forks and promotes fork repair and restart<sup>56</sup>.

A particularly perplexing relationship is that of RS and origin firing. While the ATR-CHK1 pathway inhibits firing of new origins by inhibiting DDK-CDC7<sup>57</sup> and CDK1<sup>58</sup>, RS has also been shown to increase origin firing. Along these lines, the rate of origin firing and replication speed seem to be inversely correlated, meaning that dormant origins are induced after replication stress, and a fork slowdown ensues upon dormant origin firing<sup>44</sup>. One reason for RS-induced dormant origin firing is to allow completion of replication in a timely manner despite reduced fork speed<sup>59–61</sup>. One proposed explanation for origin firing both increasing and decreasing upon RS is that dormant origins in actively replicating DNA regions are fired upon RS to rescue adjacent stalled forks, while dormant origins in non-replicating regions are suppressed<sup>62</sup>. Another aspect might be dosage dependency. For instance, the ATR-CHK1 pathway is activated to a different extent depending on the amount of exposed single-stranded DNA. As such, low doses of replication stress might be more permissive for dormant origin firing. In line with this notion, low levels of replication stress escape the checkpoint, meaning that ATR-CHK1 pathway is not fully activated, and are able to complete replication despite decreased fork speed<sup>63</sup>.

#### 1.2.4. Replication fork remodeling and repair pathways elicited by replication stress

The replication forks are highly plastic and amenable to remodeling upon RS<sup>64</sup>. This includes changes in the composition of the replisome and rearrangements of nucleic acid structures at and around the forks. Remodeling serves to stabilize forks and enable their repair, but can also be a source of DNA damage and genome instability if the machinery required for fork protection is mutated or missing. Major pathways of fork remodeling and repair include fork reversal, translesion synthesis, template switching and repriming<sup>65</sup>.

During fork reversal, the forks are turned into four-way (Holliday) junctions by the activity of non-redundant DNA translocases HLTF, ZRANB3, SMARCAL1<sup>66</sup> and PICH<sup>67</sup>. Multiple proposed scenarios aim to explain the role of fork reversal. If DNA damage or mismatched

nucleotides are incorporated into DNA, fork reversal can serve to hybridize the damaged DNA with the parental DNA strand, thus enabling repair using template information. On the other hand, Holliday junctions are templates for structure-specific DNA nucleases, which can turn them into double-strand breaks (DSBs), allowing for rescue of stalled forks by break-induced replication (BIR)<sup>68</sup>. Interestingly, fork reversal can also regulate the rate of fork progression. This is evidenced by observations that replication stress not only causes reversal of stalled, but also of ongoing forks<sup>69</sup>, suggesting it might act as a genome-wide means to adjust fork speed, possibly to allow extra time for repair or avoid encounters of replication machinery with damaged DNA.

The ends of the reversed forks need to be protected by specialized protein machineries to avoid nuclease-mediated resection. Major fork protectors include the tumor suppressor proteins BRCA1 and BRCA2<sup>70</sup>, although plenty more have been described. If these factors are mutated or missing, they allow nascent DNA degradation by nucleases such as MRE11, EXO1<sup>68</sup> and DNA2<sup>71</sup>. Nascent DNA degradation has been proposed as one of the main vulnerabilities of BRCA-mutated tumors, allowing for design of synthetic lethal therapies<sup>72</sup>.

Translesion synthesis (TLS) utilizes specialized DNA polymerases with relaxed nucleotide pairing requirements, such as Pol $\eta$ , Pol $\kappa$ , Pol $\iota$ , Pol $\zeta$  and REV1. It thus allows DNA synthesis over damaged DNA, which is however often mutagenic, as the correct template is not available<sup>73</sup>. Template switching (TS) denotes a pathway in which the synthesis of nascent DNA is continued on the sister chromatid upon encountering a fork block, such as a bulky adduct<sup>74</sup>. The process entails homologous recombination (HR), requiring the RAD51 filament-based homology search, DNA synthesis from the sister chromatid template, branch migration and resolution of Holliday junctions.

Finally, repriming refers to initiation of leading-strand replication immediately past the stalled fork using the specialized DNA polymerase PRIMPOL<sup>75</sup>. Repriming results in daughter-strand gaps, regions of ssDNA flanked by dsDNA. Daughter-strand gaps often contain lesions that caused fork stalling in the first place, and that need to be repaired post-replicatively using TLS or TS<sup>76</sup>. While this pathway allows for continued replication past the lesion without requiring prior repair, daughter-strand gaps are also structures

vulnerable to nuclease-mediated expansion and DSB formation, and have been identified as the underlying cause of synthetic lethality between PARP1 inhibitors and BRCA1/2 mutations<sup>77,78</sup>. In addition, extensive use of repriming increases mutagenicity, as it can employ TLS for post-replicative repair. Importantly, different fork remodeling and repair pathways are jointly regulated to ensure the choice of the appropriate pathway based on the identity of the underlying lesion, duration of fork stalling and the availability of the necessary pathway-specific proteins<sup>79</sup>.

### 1.2.5. Replication stress as a source of genome instability

One of the key features of RS is the increase in genome instability (GI), evident by the recurrent changes to the genetic material. A subset of GI is termed chromosome instability or CIN, and can be further separated into numerical/whole-chromosome CIN (W-CIN) and structural CIN (S-CIN). W-CIN refers to gains or losses of whole chromosomes, while S-CIN refers to changes in chromosome sequences as a result of indels, substitutions and translocations<sup>80</sup>. Interestingly, RS can induce both W-CIN and S-CIN, although likely through distinct mechanisms<sup>81</sup>. While W-CIN is thought to occur as a result of chromosome mis-segregation through processes such as increased microtubule instability<sup>82</sup> or defects in centrosome integrity<sup>83</sup>, S-CIN is more associated with mutagenic DNA repair processes, such as TLS, repriming<sup>84</sup>, mitotic DNA synthesis (MiDAS) and resolution of DNA bridges<sup>85</sup>. S-CIN is particularly common at specific genomic locations called the common fragile sites (CFSs), which were first described cytogenetically as gaps, breaks or constrictions on metaphase chromosomes<sup>86</sup>. CFSs are a result of under-replication at difficult-to-replicate regions, such as secondary DNA structures, tandem repeats or origin-poor regions with long genes transcribed throughout interphase. They are found in all individuals in cells subjected to mild RS. CFSs are causal for neurodegenerative syndromes such as the Fragile X syndrome, and are recognized as a driver of GI in cancer cells<sup>87</sup>.

RS and CIN are tightly linked with tumors, and are thought to promote both tumor induction and evolution<sup>88</sup>. While sources of RS in pre-neoplastic lesions and tumors are often difficult to clarify, increased expression of some of the most common oncogenes, such as MYC, RAS and Cyclin E, definitely plays a role<sup>89</sup>. Mutations in tumor suppressors, such as BRCA1 and BRCA2, are also associated with inability of cells to repair RS-associated

lesions<sup>65</sup> and consequent CIN induction. Increasingly, R-loops and G-quadruplexes (G4s) are recognized as cancer-relevant sources of RS, for example in hematological tumors such as acute myeloid leukemia<sup>90</sup>. While we often focus on disease-relevant negative consequences of RS, it is worth asking whether cells “permit” low levels of RS and mutagenicity because they bring a potential advantage. From an evolutionary perspective, RS could be an important driver of genome evolution through events such as gene duplication<sup>91</sup>.

## **1.3. R-loops**

### **1.3.1. Transcription**

Aside from serving as a storage of genetic information, DNA fulfills its role by allowing transcription of genes into different classes of RNAs, some of which are translated into proteins. Transcription is carried out by three classes of DNA-dependent RNA polymerases – RNA Pol I, Pol II and Pol III. The majority of protein-coding genes are transcribed into pre-mRNA using Pol II, whereas pre-rRNA genes are transcribed in the nucleoli using Pol I, and tRNAs and other classes of non-coding RNAs are transcribed by Pol III<sup>92</sup>. Pol II-mediated transcription can be divided into initiation, promoter clearance, elongation and termination. During initiation, the pre-initiation complex (PIC) composed of RNA Pol II and various transcription factors is assembled at gene promoters, ~30 bp upstream of the transcription start site (TSS), by binding to defined DNA sequences, such as the TATA box<sup>93</sup>. PIC assembly and interactions with gene enhancers are modulated by a multi-subunit complex called the mediator<sup>94</sup>. As part of the PIC, transcription factor TFIIF, which includes the catalytic subunit CDK7, hyper-phosphorylates the C-terminal domain (CTD) of the major Pol II subunit RPB1 at Ser 5 and Ser 7<sup>95</sup>, facilitating transition from initiation to promoter-proximal pausing by interrupting interactions with the mediator<sup>96</sup>. Pausing serves as a regulatory step to allow quick changes in gene expression in response to stimuli<sup>97</sup>. It is mediated by the Negative Elongation Factor (NELF) complex, and eventually Pol II is released into elongation through phosphorylation of NELF and hyper-phosphorylation of the CTD of RPB1 at Ser 2 triggered by the Positive Transcription Elongation Factor (p-TEFb), including the catalytic subunit CDK9<sup>98</sup>. Termination is accompanied by 3' end cleavage and polyadenylation (polyA tailing), which not only enhances termination, but also regulates transcript stability, export to cytoplasm

and translation<sup>99</sup>. During elongation, previously synthesized segments of pre-mRNA are already bound by machineries facilitating splicing, modification (for example, m6A), secondary structure formation and export (TREX-THO complex), with steps of these processes happening either co-transcriptionally or post-transcriptionally.

### 1.3.2. Definition and sources of R-loops and RNA-DNA hybrids

R-loops are three-stranded nucleic acid structures consisting of an RNA-DNA hybrid and a displaced DNA strand. They are usually formed co-transcriptionally, due to nascent RNA hybridizing with the complementary template DNA<sup>100</sup>. This is favored by negative supercoiling behind the transcribing RNA polymerases and is thought to occur stochastically. Since the nascent RNA hybridizes with the locus from which it has been synthesized, this type of an RNA-DNA hybrid is called *in cis*. The level of transcription at a gene locus strongly positively correlates with the amount of R-loops<sup>101</sup>. Transcribed GC-rich regions are particularly prone to R-loop formation because the displaced DNA strand can form G-quadruplexes (G4s), which stabilizes RNA-DNA hybrid opposite the G4<sup>102</sup>. Additionally, Pol II pausing also favors R-loop formation, as it increases the chance of nascent RNA hybridizing with complementary DNA<sup>103</sup>. Within transcribed genomic regions, R-loops are most common at promoters, transcription start sites and termination sites<sup>104</sup>, where they serve important functions. Although we usually consider Pol II to be a major source of R-loops, Pol I and Pol III transcriptional activity also results in R-loop formation<sup>105</sup>, in part because of their high transcription rates.

Direct visualization of R-loops using native electron microscopy revealed that genomic R-loops range in size from 30 to 3000 base pairs (bp), with the average size around 180 bp<sup>106</sup>. The same study estimated that a maximum of 0.009% of the genome or around 290 kb is occupied by R-loops, which is much more conservative than the genomic approaches reporting up to 5% of the R-loop-covered genome<sup>101</sup>. This discrepancy in estimates likely stems from the different methodologies used. In any case, R-loops are quite a prevalent secondary DNA structure and, interestingly, do not conform to either the B-form of dsDNA, nor the A-form of dsRNA, instead forming a mixed A/B type structure<sup>107</sup>. Co-transcriptional R-loops have an estimated half-life of 10-20 minutes<sup>101</sup>. This suggests that R-loops are turned over within minutes and their half-life coincides with that of the

promoter-proximal-paused Pol II<sup>108</sup>, suggesting that their existence is compatible with dynamics or a regular transcription cycle.

RNA-DNA hybrids *per se* do not necessarily need to form at dsDNA. In other words, ssDNA is also a common template for hybrid formation. For instance, one of the most common genomic sources of hybrids is the replication cycle, in particular Okazaki fragment formation, which includes RNA-primed DNA templates<sup>109</sup>. Moreover, misincorporation of ribonucleotide triphosphates (rNTPs), most commonly by polymerase  $\epsilon$ , results in “mini-hybrids”<sup>104</sup>, and is one of the most common sources of genomic DNA damage<sup>110</sup>. Finally, multiple sources report RNA-DNA hybrids at DSBs<sup>111</sup>. Resection was found to be required for hybrid formation, suggesting the existence of DNA damage-induced long non-coding RNAs (diIncRNAs) paired with resected DNA ends, forming a hybrid rather than an R-loop, and influencing repair of damaged DNA<sup>112</sup>.

### 1.3.3. Physiological roles of R-loops

#### 1.3.3.1. R-loops at repetitive DNA sequences

R-loops are not mere byproducts of transcription, but take on important functions. They are enriched at repetitive genomic regions, such as telomeres, centromeres, retrotransposons and ribosomal DNA (rDNA)<sup>104</sup>. At chromosome ends called telomeres, which are in vertebrates characterized by tandem repeats of the 5'-TTAGGG-3' sequence, R-loops are formed by a class of long non-coding RNAs (lncRNAs) called telomere repeat-containing RNAs (TERRA). TERRA hybridizes with the C-rich telomeric DNA strand, which is likely potentiated by G4 formation at the displaced G-rich strand<sup>113</sup>. Similarly to hybrids formed at DSBs, TERRA drives homologous recombination in a telomere maintenance pathway termed alternative lengthening of telomeres (ALT)<sup>114</sup>. Centromeric loci also express lncRNAs that hybridize with centromeric DNA *in cis*. Centromeric R-loops are particularly enriched in mitosis and enable accurate chromosome segregation through an ATR- and Aurora B-driven pathway<sup>115</sup>. Mechanistically, the displaced DNA strand of centromeric R-loops recruits RPA and subsequently activates ATR in an Aurora A-dependent manner. ATR in turn facilitates Aurora B activation, which suppresses lagging chromosomes.

Detection of R-loops by immunofluorescence using multiple strategies reveals that nucleoli, regions where Pol I-mediated transcription of pre-rRNA from rDNA repeats takes

place, are nuclear regions most enriched in R-loops<sup>116</sup>. The rDNA loci are interspersed by intergenic spacers (IGSs), with both regions being prone to R-loop formation. At rDNA promoters, characterized by G-rich CpG islands, R-loop formation prevents DNA methylation and locus silencing, thus supporting production of rDNA<sup>117</sup>. This is a good example of positive roles of promoter-bound R-loops on transcription, which has also been observed across other genomic CpG islands<sup>117</sup>. On the other hand, at IGSs, which are transcribed in the antisense direction by Pol II, persistent R-loops form a shield preventing Pol I-mediated sense transcription. Thus, through restricting Pol I activity to rDNA only, R-loops at IGSs ensure appropriate nucleolar morphology and ribosome biogenesis<sup>118</sup>.

#### 1.3.3.2. R-loops at transcription termination sites

Aside from roles at promoters, R-loops are also abundant and functionally relevant at termination sites<sup>101</sup>. Faulty termination can lead to transcription past the TTS, a phenomenon called read-through transcription. Read-through is particularly dangerous in gene-dense regions, as it can affect downstream gene expression by transcriptional interference<sup>119</sup>. A common strategy of termination is RNA polymerase stalling at a G-rich sequence downstream of the polyA sequence<sup>120</sup>. A genome-wide mapping analysis found that around 2000 G-rich termination sites are occupied by R-loops<sup>121</sup>. Although the exact mechanisms by which R-loops aid termination are still discussed, they include triggering Pol II backtracking, Pol II arrest due to torsional stress and recruitment of termination-promoting factors, such as BRCA1, SETX, DDX5, DHX9 and XRN2<sup>104</sup>.

#### 1.3.3.3. R-loops in antisense transcription

LncRNAs generated by antisense transcription can form R-loops and often recruit transcription activators or repressors. For instance, lncRNA *ANRASSF1* is produced from the 3'-end of the *RASSF1* locus in the antisense direction and recruits the Polycomb repressive complex 2 (PRC2) to silence the *RASSF1A* promoter through H3K27 trimethylation<sup>122</sup>. An example of an R-loop acting *in trans* and resulting in deposition of activating histone marks is the *GATA3-AS1* lncRNA. It is expressed from the *GATA3* locus and forms an R-loop 3 kb upstream. It upregulates *GATA3* expression by recruiting MLL/KMT2A to the locus, resulting in deposition of an activating mark – H3K4 trimethylation<sup>123</sup>. Additionally, R-loops can promote DNA demethylation at CpG islands through antisense RNAs. The lncRNA *TARID*, produced in the antisense direction from

the *TCF21* locus, forms a promoter R-loop that recruits the direct R-loop binder GADD45A. Through direct protein-protein interactions, GADD45A recruits the DNA demethylase TET, which removes DNMT3-mediated CpG promoter methylation, thereby enabling expression from the *TFC21* locus<sup>124</sup>.

#### 1.3.3.4. R-loops and RNA-DNA hybrids in DNA repair

Multiple labs have detected RNA-DNA hybrids at DSBs and have shown they have direct roles in DSB repair. It is, however, less clear whether three-stranded R-loop structures are also formed at DSBs<sup>104</sup>. Multiple non-mutually exclusive models of hybrid production at breaks were proposed. Increased pausing of Pol II, a decrease in elongation rates and premature transcriptional termination at DSBs could result in co-transcriptional stabilization of hybrids<sup>111</sup>. Along these lines, genome-wide mapping of RNA-DNA hybrids following induction of DSBs revealed their accumulation primarily in regions occupied by Pol II before break induction, arguing for a model in which pre-existing RNAs hybridize with DNA at breaks<sup>125,126</sup>. On the other hand, *de novo* transcription from 3'-ends of resected DSBs is evidenced by recruitment of the PIC, the mediator complex, CDK9 and Pol II to DSBs<sup>127</sup>. This results in production of diIncRNAs<sup>112</sup> that favor repair by homologous recombination.

Regardless of the source of RNA-DNA hybrids at DSBs, they can contribute to repair in multiple ways. RNA-DNA hybrids were shown to both prevent<sup>128</sup> and favor<sup>129</sup> nuclease-mediated resection at DSBs. Downstream of resection, hybrids seem to favor RAD51 nucleofilament formation<sup>130,131</sup>, a step essential for strand invasion part of the HR<sup>132</sup>. However, RNA-DNA hybrids need to be removed prior to RAD51 loading<sup>125,129</sup>, highlighting their transient nature and tight regulation at DSBs. Aside from classical views of HR, alternative pathways of DSB repair are emerging, such as the RNA-templated repair. Such repair is based on the following premises: (1) mRNA produced from the DSB locus before the DSB induction can span both sides of the DSB, providing a possible template for repair<sup>133</sup>; (2) the translesion synthesis polymerase Polζ is an RNA-templated DNA polymerase<sup>134</sup>; (3) RAD52 and RPA favor annealing of mRNA with complementary DNA at DSBs. Therefore, DNA synthesis from the minimally resected 3'-end of the DSB can be initiated by Polζ in a RAD52-dependent manner, using hybridized RNA as the

template<sup>134</sup>. This type of repair is particularly suitable for G0/G1 phase, when sister chromatids are not available for classical HR-mediated repair<sup>135</sup>.

#### 1.3.4. Role in genome instability

So far, I have highlighted functional roles of R-loops. However, a recurring theme in R-loop biology is the transient nature of R-loops and RNA-DNA hybrids, and the need for their regulation and removal. Accordingly, R-loops can impede major DNA- and RNA-related processes that happen on chromatin, such as DNA replication and repair, and transcription<sup>136</sup>. In cases when R-loop levels are elevated and associated with negative functional outcomes, we consider R-loops aberrant, unscheduled, or even pathological<sup>136</sup>. Many of the negative effects attributed to R-loops stem from the fact that they increase replication stress and replication-associated DNA damage<sup>137</sup>. In addition, even in non-dividing cells, where replication-associated processes should not play a major role, R-loops can cause transcription-associated DNA damage<sup>138</sup>.

It is widely recognized that ssDNA is more vulnerable than dsDNA to DNA damage<sup>139</sup>. Stabilization of R-loops can thus increase DNA damage by leaving the displaced ssDNA exposed, rendering it more prone to spontaneous chemical modifications, and more accessible to chemical mutagens, oxidative damage, base-modifying enzymes or nucleases<sup>137</sup>. Aside from that, conflicts between the replication and transcription machineries have lately garnered a lot of attention<sup>140</sup>. As both machineries share the same template, they are normally temporally and spatially well separated. Circumstances like oncogene-induced premature S-phase entry and dormant origin firing increase the likelihood of these conflicts<sup>47</sup>. Mechanistically, this is thought to occur through replication taking place on genes that are still actively transcribing. There are two main possible scenarios: the replication and transcription machineries travelling in the opposite direction towards each other (head-on collisions), and both machineries traveling in the same direction (co-directional conflicts). Head-on collisions were shown to be much more dangerous, as they lead to R-loop accumulation, activation of the ATR pathway, and an increase in DSBs<sup>141</sup>. On the other hand, co-directional conflicts activate ATM, and decrease R-loop levels, possibly by the action of the replicative helicase MCM2-7, which can unwind RNA-DNA hybrids<sup>142</sup>. Alternatively, PrimPol could reprime replication

downstream of the R-loop in case of co-directional transcription-replication conflicts (TRCs), as is the case at the GAA repeats<sup>143</sup>.

Importantly, R-loops are necessary for induction of DSBs upon head-on TRCs. Activation of ATR by R-loops requires fork reversal and the structure-specific endonuclease MUS81<sup>144</sup>, suggesting that forks reverse upon the TRC, and are cleaved by MUS81 to produce a single-ended DSB. Another pathway connecting R-loops to DSB induction is the transcription-coupled nuclear excision repair (TC-NER). R-loops can be processed by the TC-NER endonucleases XPG and XPF, which were shown to create adjacent single-strand breaks, helping to excise the R-loop from the genome, and thereby creating a DSB<sup>145</sup>. Moreover, a recent surprising report found that XPG/XPF-processed nuclear R-loops are a source of cytoplasmic RNA-DNA hybrids, suggesting that they are exported or diffuse from the nucleus to the cytoplasm. In line with cytoplasmic nucleic acid species being immunogenic, these hybrids activate the cGAS-STING pathway, leading to cell death through the innate immune response<sup>146</sup>, a mechanism that likely contributes to R-loop-related diseases.

### 1.3.5. R-loop removing enzymes

Considering the deleterious potential of R-loops and RNA-DNA hybrids, it is not surprising that they are tightly regulated by multiple specialized machineries. Main enzyme classes involved in suppression of RNA-DNA hybrids are helicases, nucleases, topoisomerases and translocases. Many additional factors that do not possess these enzymatic activities can also suppress R-loops, as will be described below.

#### 1.3.5.1. R-loop helicases

Among helicases, a large family called the DEAD-box (DDX) and the DEAH-box (DHX) contains several members known to unwind R-loops. For instance, DHX9 binds RNA-DNA hybrids and unwinds R-loops<sup>147,148</sup>. Along with a couple of other DDX helicases, it associates with the PCNA unloader ATAD5 to suppress R-loops during replication<sup>149</sup>. DDX5<sup>128</sup>, DDX19A<sup>150</sup>, DDX21<sup>151</sup> and DDX39B<sup>152</sup> were also implicated in the R-loop resolution. Our group has demonstrated that another DEAD-box helicase, DDX41, suppresses aberrant R-loops and consequent DSBs at gene promoters. Depletion of DDX41 leads to increased replication stress, dependency of cancer cells on ATR and inflammatory signaling. Considering that DDX41 mutations are implicated in acute

myeloid leukemia (AML), we proposed that R-loop accumulation might be involved in the etiology of AML<sup>153</sup>. Accordingly, using zebrafish models, Weinreb *et al.* found that Ddx41 regulates the number of hematopoietic stem progenitor cells (HSPCs) and constrains R-loop levels. Moreover, Ddx41 insufficiency led to increased cGAS-STING inflammatory signaling, which is associated with hyperproliferation of HSPCs<sup>154</sup>. These findings substantiate previously discussed roles of R-loops in replication stress, DNA damage induction, inflammatory signaling and disease.

A well-recognized and well-conserved RNA:DNA hybrid helicase is Senataxin (SETX in humans, or Sen1 in yeast<sup>155</sup>). SETX removes R-loops at transcription termination sites, thereby promoting release of nascent transcripts in a manner that depends on the RNA exonuclease XRN2<sup>156</sup>. SETX is also recruited to DSBs that form in transcriptionally active loci, favoring recruitment of RAD51, preventing aberrant joining of DNA ends and thereby translocations<sup>125,157</sup>. Notably, SETX is also present in the nucleoli, where it binds IGS regions, sites of Pol II-mediated R-loop production. SETX regulates levels of R-loop-forming lncRNAs at IGSs, thereby contributing to nucleolar morphology<sup>118</sup>. SETX is particularly important from a disease perspective, as its gain or loss of function mutations contribute to two neurological disorders: Type 2 ataxia with oculomotor apraxia (AOA2) and juvenile amyotrophic lateral sclerosis (ALS4)<sup>158</sup>. Changes in R-loop homeostasis were observed in AOA2 and ALS4 patients and likely contribute to disorder phenotypes.

#### 1.3.5.2. R-loop nucleases

Two *bone fide* nucleases of the Ribonuclease H (RNase H) family have the ability to specifically bind RNA-DNA hybrids and degrade their RNA moiety: RNase H1 and H2. As RNase H1 is discussed in detail in the section 1.4, I will here focus on RNase H2. It is a trimeric nuclear complex containing the catalytic subunit RNase H2A, and two accessory subunits, RNase H2B and H2C. The catalysis takes place via a two-metal ion mechanism using the active site situated on the H2A subunit<sup>159</sup>. The H2B subunit is thought to have a role in protein-protein interactions, evidenced by its PCNA interacting protein-box (PIP-box) region<sup>160</sup>. The H2C is thought to have a largely structural role, as it is connecting H2A and H2B<sup>159</sup>. RNase H2 associates with the replisome through PIP-box-mediated interactions with PCNA. This might be relevant for its contribution to removing RNA primers during Okazaki fragment maturation<sup>161</sup>, as well as its role in ribonucleotide

excision repair (RER)<sup>162</sup>. Its essential role in removal of mis-incorporated ribonucleotides is substantiated by the fact that, in the absence of RNase H2 function, topoisomerase Top1 can aberrantly process rNMPs, leading to deletions and DSBs<sup>163–165</sup>. In yeast, RNase H2 expression is cell cycle-regulated and peaks in late S and G2 phase, in line with its post-replicative requirements in RER and R-loop removal<sup>166</sup>. RNase H2 loss results in a stronger genome instability phenotype in yeast than RNase H1 loss<sup>167</sup>, likely because RNase H2 is thought to have a broader role in RNA-DNA hybrid removal, and is additionally indispensable for RER. Mutations in RNase H2 cause the Aicardi–Goutières syndrome (AGS), a rare inflammatory neurodevelopmental disorder<sup>168</sup>. Additionally, the autoimmune disease systemic lupus erythematosus is also characterized by recurrent RNase H2 mutations<sup>169</sup>, and shares disease features with AGS<sup>170</sup>. Disease pathology of both of these disorders involves inflammatory interferon signaling, which likely occurs as a result of aberrant sensing or accumulation of self-derived immunogenic nucleic acids species<sup>171</sup>.

#### 1.3.5.3. R-loop-suppressing topoisomerases and translocases

Topoisomerases are cellular enzymes that regulate the topological state of DNA and RNA<sup>172</sup>, and are able to resolve topological stress that results from nucleic acid transactions. Topoisomerase 1 (TOP1) introduces DNA nicks, allowing the DNA duplex to untwist<sup>173</sup>, thereby relieving both positive and negative supercoils during replication and transcription<sup>174</sup>. As previously mentioned, transcription leads to negative supercoiling behind the RNA polymerases, which favors R-loop formation. Furthermore, R-loops are especially problematic at head-on TRCs. Accordingly, TOP1 prevents TRCs and replication stress at R-loop-enriched transcription termination sites of highly expressed genes<sup>175</sup>. Moreover, loss of yeast Top1 leads to R-loop stabilization within Pol I-transcribed rDNA repeats, which is exacerbated by the loss of RNase H activity<sup>105</sup>.

A recent study implicated another class of enzymes, translocases, in R-loop resolution<sup>176</sup>. Translocases use ATP to anneal strands at DNA junctions, thereby moving the branchpoint between the dsDNA and an alternative DNA structure. Such junctions are found at stalled replication forks or transcription bubbles. Three different translocases, FANCM, ZRANB3 and SMARCAL1, were found to displace R-loops *in vitro* and suppress them *in vivo* in human cells. This suggests that, in addition to triggering fork reversal, fork

remodelers also remove R-loops, perhaps in similar situations when fork reversal is necessary (eg. at TRCs)<sup>176</sup>.

#### 1.3.5.4. Other R-loop-suppressing proteins

Productive transcriptional elongation and efficient RNA processing help to keep R-loop levels low<sup>137,177</sup>. Conversely, defects in RNA splicing lead to aberrant R-loop accumulation. This is likely because defects in splicing expose the free 5'-RNA end necessary for R-loop formation<sup>178</sup>. Additionally, excision of introns reduces complementarity of RNA with the DNA template, decreasing the likelihood of R-loop formation. Aquarius (AQR) is an RNA helicase/ATPase and an essential component of the pentameric intron-binding complex<sup>179</sup>. The activity of this complex leads to the activation of the B spliceosome<sup>180</sup>. Depletion of AQR causes strong R-loop accumulation and a consequent increase in DSBs<sup>145</sup>. It is, however, not clear if AQR is a direct RNA-DNA hybrid helicase, whether its splicing role or yet another activity cause the R-loop increase observed after its depletion. Mutations in general splicing factors SRSF2 and U2AF1 are commonly found in the myelodysplastic syndrome (MDS) and also lead to R-loop accumulation, DNA damage and ATR activation. Elevated R-loops have therefore emerged as a unifying mechanism in MDS associated with splicing factor mutations<sup>181</sup>.

Even before the discovery of the role of splicing in R-loop homeostasis, it became clear that RNA processing proteins contribute to R-loop regulation. The THO/TREX complex, which directs the export of mRNA from the nucleus to the cytoplasm, prevents R-loop accumulation and enables efficient transcriptional elongation in both yeast and human cells<sup>182,183</sup>. Mechanistically, THO promotes the recruitment of the histone deacetylase Sin3a, leading to transient histone deacetylation, which likely disables R-loop formation behind the RNA polymerase<sup>184</sup>.

Finally, two tumor suppressors, core DNA damage and fork stability factors, BRCA1 and BRCA2, have a role in R-loop homeostasis. This role likely contributes to their canonical functions in both DSB repair and fork protection. BRCA1 antagonizes 53BP1 at DSBs and thereby opposes non-homologous end joining (NHEJ) and favors HR<sup>185</sup>. Recent results by multiple groups suggest that BRCA1 is a direct RNA-DNA hybrid binder and is recruited to DSBs by hybrids<sup>131</sup>. BRCA1 is known to favor BRCA2 recruitment to resected DSBs<sup>186</sup>, which in turn results in RAD51 loading<sup>187</sup> and homology search. Importantly, BRCA2

seems to recruit RNase H2 to DSBs<sup>131</sup>, helping to remove the hybrids, presumably to enable RAD51 loading. Therefore, recent models suggest that BRCA1 is recruited to DSBs by hybrids, and that the hybrids are in turn removed in a BRCA2-dependent manner<sup>188</sup>. Additionally, BRCA1 recruits the helicase SETX to transcription termination sites to resolve R-loops and prevent R-loop-associated single-strand breaks<sup>189</sup>. Whether BRCA1 also recruits SETX to sites of DSBs is less clear. BRCA1 also seems to suppress R-loops at promoter-proximal sites<sup>190</sup>. In neuroblastoma cells, where the oncogenic transcription factor MYCN is expressed, BRCA1 is recruited to sites of promoter-proximal pausing in a MYCN-dependent manner to aid R-loop removal and enable transition into elongation<sup>191</sup>. Altogether, these and many other factors lacking enzymatic activities necessary for R-loop removal maintain R-loop levels through more indirect mechanisms.

**Figure 2: R-loop-removing enzymes.**

## 1.4. RNase H1

### 1.4.1. Domain composition, localization and conservation

The RNase H enzymes were discovered and isolated from calf thymus samples in the laboratory of Peter Hausen in Tübingen (1969), and given the name indicating the RNA-DNA *hybrid* specificity<sup>192</sup>. RNase H was found in crude isolates of RNA polymerase, decreasing its ability to synthesize RNA from denatured DNA templates five-fold. Along with RNase H2, RNase H1 is the main nuclease able to degrade the RNA strand of the RNA-DNA hybrids in both eukaryotes and prokaryotes. Members of the RNase H family can be found in essentially all organisms, including bacteria and archaea<sup>193</sup>. Human

RNase H1 consists of the N-terminal mitochondrial localization signal (MLS), followed by the hybrid-binding domain (HBD). The catalytic domain (also called the H-domain) is located at the C-terminus, with the unstructured linker connecting the HBD and the catalytic domain<sup>194</sup>. The relatively long linker (around 60 amino acids) allows the catalytic domain to access the hybrid substrates at multiple sites, which may increase enzyme processivity<sup>195</sup>. The full length enzyme is a 286-amino acid protein (32 kDa) expressed ubiquitously in human cells and tissues. Two isoforms of RNase H1 are present in human, both expressed from the same mRNA, the shorter one lacking the MLS. Synthesis of the shorter isoform occurs by alternative translation initiation site at M27, the initial methionine of the HBD<sup>196</sup>. In line with the domain composition, the longer isoform localizes to the mitochondria (mtRNase H1), whereas the shorter localizes to the nucleus (nucRNase H1 or M27-RNase H1). The latter is expressed 7-fold higher than the former, which was explained by the more efficient translational initiation from M27 than from M1. The low expression of mtRNase H1 might be an evolutionary feature essential to avoid toxicity resulting from mitochondrial overexpression<sup>196</sup>. Strong nucleolar enrichment of the nuclear isoform is mediated by the HBD<sup>197</sup>. The truncated version containing only the linker and the catalytic domain localizes to the nucleoplasm, but is excluded from the nucleoli, suggesting that these two domains are sufficient for nuclear localization, although a typical nuclear localization signal (NLS) is missing. Interestingly, RNase H1 is very well conserved. The human version has considerable sequence similarity (33.6% amino acid identity) even with the *E. coli* RNase H1<sup>198</sup>. As expected, the structured domains (HBD and the catalytic domain) are better conserved than the linker.

#### 1.4.2. HBD – the hybrid-binding function of RNase H1

The architecture of RNase H1 is well suited for recognition and removal of RNA-DNA hybrids. The human HBD comprises around 50 amino acids and enhances the processivity of RNase H1<sup>199</sup>. Based on the mutational analysis and biochemical binding assays, three amino acids (W43, K59 and K60) of the HBD have emerged as the critical determinants of the heteroduplex positioning<sup>200</sup>. While K59 and K60 bind the heteroduplex, W43 is responsible for correct positioning of RNase H1 on the substrate for catalysis. Structural models of the HBD with a 12-bp hybrid substrate obtained by Cryo-EM explained HBD's 25-fold preference for hybrids over other nucleic acid substrates by

examining residues critical for binding to either the RNA or the DNA moiety<sup>195</sup>. The RNA-binding loop (D51-A56) mediates binding of the ribose 2'-OH groups to main chains of R52 and A55. The aromatic patch (W43 and F58) is structurally complementary with the DNA strand and critical for hybrid specificity, as substituting deoxyribose with the ribose results in a sterical clash. K60 is one of the few residues directly interacting with the DNA phosphates. These results further substantiate the critical role of the WKK residues in hybrid recognition.

### 1.4.3. Catalytic domain – the hybrid-degradation function of RNase H1

The catalytic domain provides the endonuclease function and consists of around 150 residues, including four conserved carboxylates (D145, E186, D210, and D274) forming the active site, the former three being essential for the enzymatic activity<sup>201</sup>. Similarly to RNase H2, catalysis occurs through a two-metal ion mechanism. Mg<sup>2+</sup> is the preferred ion, and Mn<sup>2+</sup> has an inhibitory effect in the presence of Mg<sup>2+</sup><sup>198</sup>. Unlike RNase H2, which can remove single ribonucleotides from dsDNA, RNase H1 requires at least a 6-bp long hybrid substrate, but the optimal cleavage position is 8-12 nucleotides from the 5'-RNA-3'-DNA terminus<sup>202</sup>. While the HBD specializes in hybrid binding, the catalytic domain also contacts both RNA and DNA strands of the hybrid using well-conserved residues in multiple binding pockets that primarily contact the minor groove<sup>203</sup>.

**Figure 3: Structure of human RNase H1.**

AlphaFold3-modeled structure of human nuclear isoform of RNase H1 in complex with a 12mer RNA:DNA hybrid rendered in PyMol. The main structural features that enable hybrid binding and cleavage are highlighted. Two Mg<sup>2+</sup> ions positioned in the active site are shown.

#### 1.4.4. Biological roles and regulation

The mammalian RNase H1 has been best studied in the mitochondria. It is essential for processing of RNA primers during the replication of mitochondrial DNA (mtDNA). Likewise, it is involved in the completion of mtDNA replication. In cells lacking RNase H1, linear mtDNAs with deletions are formed instead of proper circular mtDNA<sup>204</sup>. As the complete knockouts of the mouse *Rnaseh1* gene are embryonic lethal<sup>205</sup>, conditional knockouts in the mouse heart have been developed to study the RNase H1 function *in vivo*<sup>204</sup>. In the conditional knockout, mitochondrial transcripts are steadily lost during development. While this is likely a consequence of the function of RNase H1 in the replication of mtDNA, RNase H1 also reportedly functions in mitochondrial transcription and translation by regulating mitochondrial mRNAs, rRNAs, and the 7S non-coding RNA<sup>206</sup>. Studying human RNase H1 is disease-relevant, as mutations in the catalytic domain lead to the adult-onset mitochondrial encephalomyopathy<sup>207</sup>, also known as the

Autosomal recessive progressive external ophthalmoplegia (PEO) with mitochondrial DNA deletions-2. Recently, the first patients with a mutation in the HBD (Y29C) were identified, displaying symptoms of PEO. Interestingly, this mutation was shown to increase the RNase H1 activity, suggesting that tight coordination of the mtRNase H1 activity is necessary for its mitochondrial function<sup>204</sup>.

Several studies in yeast offer valuable insights into functions of the RNase H1, and hint towards potential function of the nuclear isoform in mammalian cells. Yeast RNase H1 functions independently of the cell cycle, but seems to only degrade hybrids upon their accumulation<sup>166</sup>. The yeast *RNH1* gene can be deleted with modest increases in sensitivity to DNA-damaging agents<sup>208</sup>. Although yeast RNase H1 is able to associate with R-loops genome-wide, it removes them only at strong R-loop-forming loci<sup>209</sup>. These include Pol III-transcribed tRNA and 5S rDNA loci<sup>210</sup>. The fact that RNase H1 degrades only a subset of R-loops implies it is somehow restricted from activity, presumably by either protein-protein interactions, PTMs<sup>209</sup>, or both.

In humans, nuclear RNase H1 is present at telomeres specifically in ALT cells, where it regulates TERRA. Both depletion and overexpression of RNase H1 have negative consequences on telomere integrity in ALT cells<sup>211</sup>. Furthermore, RNase H1 interacts and co-localizes with RPA<sup>212</sup>, with HBD residues R32, R33 and R52 being important for the interaction. However, it is not clear whether this interaction is independent of nucleic acids. Along these lines, the interaction of RNase H1 with RPA depends on the presence of DNA in yeast<sup>210</sup>. *In vitro*, RPA promotes human RNase H1 association with and activity towards hybrids with a DNA overhang or R-loops<sup>212</sup>. As previously mentioned, the nuclear isoform of RNase H1 is present in the nucleoplasm and further enriched in the nucleoli. Upon inhibition of RNA Pol I, RNase H1 and hybrids are transported from the nucleoli to the perinucleolar ring structures. Moreover, after inhibition of TOP1 with camptothecin, RNase H1 is further accumulated in the nucleoli, along with the hybrids. Accordingly, depletion of RNase H1 results in the accumulation of Pol I-transcribed R-loops<sup>197</sup>. This mirrors data from yeast showing that, upon Top1 deletion, RNase H enzymes are critical for removal of Pol I-derived R-loops<sup>105</sup>.

Human RNase H1 has been detected at laser-induced microirradiation tracks, representing sites of DSBs. This suggests a potential role of RNase H1 in removal of DSB-associated hybrids. The potential impact of RNase H1 on TRCs is poorly understood, although it has recently been reported that overexpression of RNase H1 increases fork speed<sup>106</sup> and rescues fork degradation upon loss of BRCA2<sup>213</sup>, suggesting a role at replication forks.

Antisense nucleotides (ASOs) are DNA oligos that can be used to regulate gene expression and have therapeutic applications, for example in neurological disorders<sup>214</sup>. They are designed to be complementary to endogenous target cytoplasmic or nuclear RNAs, and can thus form RNA:DNA hybrids. Upon hybrid formation, the RNA is cleaved in an RNase H1-dependent manner<sup>215</sup>, thereby reducing the pool of target RNA available for translation. Therefore, a better understanding of RNase H1 biology could improve therapeutic applications of ASOs.

#### 1.4.5. A tool in R-loop biology

RNase H1 is emerging as the gold-standard tool to detect and manipulate R-loops in human cells<sup>216</sup>. The tools for hybrid detection based on RNase H1 are increasingly used because the traditional way of detecting R-loops using the S9.6 antibody has been brought into question. Namely, in addition to RNA:DNA hybrids, S9.6 seems to also recognize other RNA species in immunofluorescence approaches, evident from its sensitivity to RNase T1 treatment<sup>217</sup>.

Overexpression of RNase H1, either after transient transfection<sup>218</sup> or in inducible cell lines<sup>219</sup>, is used to remove R-loops genome-wide. This is often used to argue that the observed phenotypes are R-loop-dependent. Expression of fluorophore-tagged D210N-RNase H1<sup>212</sup> or the HBD-GFP<sup>220</sup> has been used to detect nuclear R-loops by immunofluorescence. A similar approach was developed with purified D210N-RNase H1 for use in fixed cells<sup>221</sup>. Additionally, a recent tool called RHINO consists of a GFP-tagged triple HBD and enables detection of R-loops in live cells<sup>116</sup>. Point mutations of the hybrid-binding WKK residues to alanine offer an additional convenient specificity control, which we have exploited in R-loop proximity proteomics (HBD-APEX2)<sup>153</sup>. A similar approach, based on the D210N-RNaseH1 fused to TurboID<sup>222</sup>, was concomitantly developed. Tools

based on RNase H1 are also finding use in genomic approaches to map R-loops, including the Cut&Run-based MapR<sup>223</sup> and the ChIP-seq-based R-ChIP<sup>224</sup>.

### Inducible R-loop removal

### Visualization

### Identification of R-loop-proximal proteins

### Genomic mapping of R-loops

**Figure 4: RNase H1 as a tool in R-loop biology.**

Genetically engineered RNase H1 can be used to remove or visualize R-loops *in vivo*, to map R-loop-proximal proteins or genomic regions containing R-loops.

## **1.5. Aims of this work**

In this project, we aimed to get a deeper understanding of the relationship between replication stress and the resolution of R-loops. For this purpose, we decided to investigate the phosphorylation response to replication stress, with a focus on R-loop-resolving enzymes. In the course of the project, phosphorylation of the R-loop-degrading nuclease RNase H1 emerged as a promising lead. Considering the ubiquitous use of RNase H1 as a gold-standard research tool in R-loop biology (section 1.4.5), surprisingly little is known about how it is regulated in human cells. For example, it is not clear whether the activity of human RNase H1 is simply determined by its amount, or by additional mechanisms, such as post-translational modifications and protein-protein interactions. Furthermore, it is not clear whether human RNase H1 can recognize all RNA:DNA hybrids or only a subset, and how this specificity is accomplished. Answering these and other questions will improve the design of tools based on RNase H1 and inform the users about the most appropriate tool for their end goal. From the perspective of kinase signaling, we aimed to find novel aspects of DYRK1A signaling, particularly with regards to RNA processing and R-loop biology. DYRK1A is dysregulated in disease, for example in Down syndrome. We realized that its function in RNA processing is understudied in the context of Down syndrome, and might be relevant for some of the pathologies related to this syndrome.

## 2.1.3. Solutions

Cell lysis buffer for DNA fiber assay: 200 mM Tris-HCl pH 7.4, 50 mM EDTA, 0.5% SDS

Ponceau S solution: 0.1% (w/v) Ponceau S in 5% (v/v) acetic acid

RIPA buffer: 50 mM Tris-HCl pH 7.5, 150 mM NaCl, 1% IGEPAL CA-630, 0.5% sodium deoxycholate, 0.1% SDS, 2.5 mM MgCl<sub>2</sub>

mRIPA buffer: 50 mM Tris-HCl pH 7.5, 150 mM NaCl, 1% IGEPAL CA-630, 0.5% sodium deoxycholate, 2.5 mM MgCl<sub>2</sub>

Cell extraction buffer: 10 mM Tris-HCl, pH 7.4, 100 mM NaCl, 1 mM EDTA, 1 mM EGTA, 1 mM NaF, 20 mM Na<sub>4</sub>P<sub>2</sub>O<sub>7</sub>, 2 mM Na<sub>3</sub>VO<sub>4</sub>, 1% Triton X-100, 10% glycerol, 0.1% SDS, 0.5% deoxycholate

2x Dilution buffer: 10 mM Tris/Cl pH 7.5, 150 mM NaCl, 0.5 mM EDTA

Phosphatase inhibitors: 100 mM sodium orthovanadate, 500 mM sodium fluoride, 500 mM β-glycerophosphate

Urea:thiourea solution: 6M urea / 2M thiourea in 10 mM HEPES pH 8.0

HE200 buffer: 10 mM HEPES, 200 mM NaCl, 0.05% Tween-20, 50 μM EDTA; final pH 7.5

TE40 buffer: 10 mM Tris-HCl, 40 mM NaCl, 0.05% Tween-20, 50 μM EDTA; final pH 7.5

Duplex buffer: 100 mM potassium acetate, 30 mM HEPES, pH 7.5

## 2.2. DNA oligonucleotides

Table 4: List of DNA oligonucleotides used in this study.

Name	Sequence
heliX oligo 1 (26mer)	GCGCTCGCTCACCTCCTCTACGGCCTTTATC AGTACTTGTCAACACGAGCAGCCCGTATATTCTCCTACAG CACTA
heliX oligo 2 (26mer)	GGCCGTAGAGGAGGGGAGCGAGCGC

## 2.5. Cell lines

Table 7: List of the mammalian cell lines used in this study.

ID	Cell line	Antibiotics	Source
320	HCT116		Holger Bastians, Uni Göttingen
449	HCT116:M27-RNaseH1-GFP	Puromycin	This study
450	HCT116:M27-RNaseH1-S3xA-GFP	Puromycin	This study
451	HCT116:M27-RNaseH1-S3xD-GFP	Puromycin	This study
102	U2OS:CCNE1-HA	Puromycin	Beli lab
273	U2OS:RNaseH1-3xFLAG-APEX2	G418	Beli lab
-	MEF		Jim Woodgett, LTRI Toronto
-	MEF GSK3A -/-		Jim Woodgett, LTRI Toronto
-	MEF GSK3B -/-		Jim Woodgett, LTRI Toronto

## 2.6. Methods for molecular cloning

### 2.6.1. Site-directed mutagenesis

To produce the phospho-dead (S3xA) and phospho-mimicking (S3xD) mutant of RNase H1, site-directed mutagenesis was performed on the p684 vector. Plasmids were amplified by PCR using Q5 polymerase (IMB Core Facilities) and mutant-specific primers (DNA oligo table). 5'-phosphorylation was done with T4 Polynucleotide Kinase (NEB) for 30 minutes at 37°C. Subsequent ligation was carried out by T4 DNA ligase (NEB) for 2h at RT. Cloning results were validated by sequencing (Eurofins Genomics).

## 2.7. Methods for protein analysis

### 2.7.1. SDS-PAGE and Western blotting

10-20 µg total protein lysate or immunoprecipitate were resolved on 4-12% gradients SDS-PAGE gels and transferred onto nitrocellulose membranes using the Trans-Blot Turbo system or the XCell II Blot system. Following the transfer, membranes were stained with Ponceau S and blocked for 30 min in a 3 % BSA solution in PBS supplemented with 0.1% Tween-20 (PBS-T). Membranes were incubated with primary antibodies overnight at 4°C. Following 3× 5 min washes with PBS-T, secondary antibodies coupled

to horseradish peroxidase (Agilent) were applied for 1 h at room temperature. Membranes were then washed 3× 10 min with PBS-T and developed with Immobilon ECL Ultra Western HRP Substrate and SuperSignal West Pico detection reagent. Chemiluminescence signal was recorded on ChemiDoc (Bio-Rad).

## **2.8. Methods for mammalian cells**

### **2.8.1. Mammalian cell culture**

All cells were cultured at 37°C with 5% CO<sub>2</sub> and all culture media were supplemented with 10% fetal bovine serum, 100 U/mL penicillin-streptomycin and 5mM L-glutamine. U2OS cells were maintained in Dulbecco's modified Eagle's medium (DMEM) and HCT116 cells were maintained in Roswell Park Memorial Institute media (RPMI). Mouse embryonic fibroblasts (MEFs) were maintained in DMEM (high glucose with GlutaMAX Supplement) with 10% FBS, PenStrep and 1x non-essential amino acids. The three stable HCT116 cell lines expressing RNase H1 WT, S3xA or S3xD GFP-tagged under a doxycycline (DOX)-inducible promoter were cultured in RPMI supplemented with 2 µg/mL puromycin. The stable U2OS cell line expressing Cyclin E1 under a DOX-inducible promoter were cultured in DMEM supplemented with 2 µg/mL puromycin. Cells were induced with 2 µg/mL DOX. All cells were tested on a regular basis for mycoplasma using a PCR-based method.

### **2.8.2. Lentiviral transduction**

All manipulations that included lentiviral particles were conducted in the IMB S2 laboratory. HEK293T packaging cells were transfected using a PEI:DNA ratio of 3:1 (w:w) with a packaging vector (p37), an envelope vector (p38) and either of the three transfer vectors (p684, p1163 or p1164). Media was changed from OptiMEM to complete DMEM after 7 h transfection. After 24 h, supernatant containing the viral particles was collected and filtered through a 0.45 µm PES filter. Polybrene was added to the supernatant and the mix was added to HCT116 recipient cells. After the first cell split, cells were cultured in RPMI supplemented with 2 µg/ml puromycin. During next 2 weeks, the cells were monitored and surviving colonies were downgraded using the lenti-X qPCR kit (QIAGEN). Genotype was confirmed by PCR and Western blotting.

### 2.8.3. Cell treatments and lysis

Cells were treated with 100-1000 nM APH for 24 h or other duration, as indicated in the figures; 5  $\mu$ M CX-4945, 10  $\mu$ M Harmine, 10  $\mu$ M INDY, 10  $\mu$ M Leucettine-L41 for 1 h; or 10  $\mu$ M CHIR99021 for 4 or 24 h. As a negative control an equal volume DMSO was used. Knock downs were performed for 48h with siRNase H1, siDYRK1A or siCTRL using RNAiMAX according to manufacturer's protocol. For cell lysis, cells were washed twice with PBS and lysed in RIPA buffer containing 50 mM Tris HCl (pH 7.5), 150 mM NaCl, 1 mM EDTA, 1% NP40, 0.1% Na-deoxycholate, 0.1% SDS supplemented with phosphatase inhibitors, protease inhibitor cocktail, 100 U/mL SmNuclease and 2 mM MgCl<sub>2</sub> at 4°C for 30 min on a rotation wheel. Next, samples were supplemented with sodium chloride at 450 mM and incubated for 15 min. Protein concentrations were measured using the Bradford assay and adjusted and the supernatant proteins were mixed with 4x LDS Sample Buffer supplemented with 1 mM DTT and boiled for 10 min at 95°C.

### 2.8.4. Cellular fractionation

The protocol was performed at 4°C. Cells were lysed using the mRIPA buffer supplemented with protease and phosphatase inhibitors as described above. They were incubated for 20 min rotating, then spun down for 20 min at 10000 xg. The supernatant was saved (soluble fraction). The pellet (chromatin fraction) was resuspended in the cell extraction buffer supplemented with 100 U/mL SmNuclease and 2 mM MgCl<sub>2</sub>. Protein concentrations were measured using the Bradford assay and adjusted and the supernatant proteins were mixed with 4x LDS Sample Buffer supplemented with 1 mM DTT and boiled for 10 min at 95°C.

### 2.8.5. GFP-based pulldowns

Cells were lysed as described in the section "Cell treatments and lysis". After taking 50  $\mu$ g for inputs, samples were diluted using salt-less RIPA (1:1 V:V) supplemented with protease and phosphatase inhibitors. Magnetic GFP binder agarose beads (IMB Protein Production) were equilibrated in the ice-cold 2x Dilution buffer. 25  $\mu$ l of the bead slurry was combined with an equal mass of each lysate. Samples were rotated overnight at 4°C, then washed 3x with RIPA buffer diluted 1:1 with the 2x Dilution buffer and transferred to a new tube during the last wash. Samples were boiled in 40-80  $\mu$ l of 2x NuPAGE LDS

Sample Buffer (Life Technologies) supplemented with 2 mM DTT for 15 min at 70°C. Samples were used either for Western blotting, or for interactome analysis.

### 2.8.6. Cell cycle analysis by flow cytometry

HCT116 cells were collected with trypsin, washed with PBS and fixed overnight with 70% EtOH at 4°C. Pelleting post-fixation was performed at 3500 xg. Cells were washed once in the wash/permeabilization solution (0.05% Triton-X-100 in PBS), and once in PBS with 2% BSA. To remove RNA, cells were treated for 30 min with RNase A (1 mg/ml) in PBS at RT. They were resuspended in PBS containing 1 mg/ml propidium iodide (PI). Acquisition was performed on a BD LSRFortessa flow cytometer and 40 000 cells were recorded. The 355 nm laser and 450/50 band pass filter were used for analyzing PI fluorescence. Further analysis was done using FloJo. After gating for singlets (FSC/SSC, then PI-H/PI-A) cell cycle profile was determined based on PI staining.

### 2.8.7. DNA fiber assay

HCT116 cells were labeled with 5-Chloro-2'-deoxyuridine (CldU, 30 µM) for 30 min, washed once with warm PBS, then labeled for 30 min with 5-Iodo-2'-deoxyuridine (IdU, 340 µM). Cells were treated with APH for 1.5 h, 30 min before labeling, and 2x30 min during the labeling pulses. After labeling, cells were washed once with warm and 3x with cold PBS, then trypsinized and spun down (300xg, 5 min). They were resuspended in cold PBS, counted and diluted to  $5 \times 10^5$ /ml. Labeled cells were diluted with twice the number of unlabeled cells. 4 µL of the cell suspension were mixed with 7.5 µL of the lysis buffer for fiber assay directly on the SuperFrost Plus microscopy slide (Thermo Scientific) and incubated horizontally for 9 min. The slides were then tilted at 30°–45°, allowing DNA fibers to spread to the bottom of the slide. DNA spreads were air-dried and fixed with 3:1 methanol:acetic acid overnight at 4 °C. The fibers were rehydrated 3 × 3 min in PBS, dipped once in Milli-Q water and denatured in 2.5 M HCl for 1.5 h at RT, then washed 5 × 3 min in PBS. The slides were blocked for 40 min in the blocking solution (2% BSA, 0.1% Tween-20 in PBS) and incubated with primary antibodies (mouse anti-BrdU, 1:100, BD Bioscience and rat anti-BrdU, 1:500, Abcam) at RT for 2.5 h. After 3 × 5 min washes with PBS-T, the slides were incubated with secondary antibodies (goat anti-mouse Cy3.5, Abcam and goat anti-rat Cy5, Abcam) at RT in the dark for 1 h. The spreads were washed

3 × 5 min with PBS-T, dipped in Milli-Q water, and air-dried completely in the dark. The slides were mounted using Prolong Gold AntiFade mountant (Thermo Scientific), imaged with Visiscope 5-Elements Spinning Disc Confocal microscope (Visitron Systems, Germany) (magnification: ×60 Water immersion objective with ×2 extra magnification; laser lines and corresponding emission filters: 640 nm, 692/40 and 561 nm 623/32) and quantified using the Fiji/ImageJ software.

#### 2.8.8. Fluorescent microscopy using Opera Phenix

Knockdowns in HCT116 cells were performed in 6-well plates and cells were re-plated into PhenoPlates (Perkin Elmer) after poly-lysine coating. All washes were performed in PBS. Cells were washed 2× and fixed with ice-cold methanol for 5 min at –20°C, washed 3x, and permeabilized with Triton X-100 (0.3%) for 5 min at room temperature, followed by 2x washes. Cells were then blocked for 30 min with 3% BSA in PBS-T. Incubation with HBD-AF647 (250 nM) diluted in the blocking buffer supplemented with 1 µg/ml Hoechst 33342 was performed overnight at 4 °C and followed by 3× washes with PBS-T. Cells were kept at 4 °C in PBS until imaging. Imaging was performed with an Opera Phenix (PerkinElmer) microscope using a ×40 1.1NA water objective. Image analysis was performed by using Harmony High-Content Imaging and Analysis Software (version 4.4, PerkinElmer). Standard building blocks allowed for nuclei segmentation based on the Hoechst signal and cells on the edges of the field were excluded. Mean intensity measurements were performed for maximum projections and spot detection was calculated by using algorithm B. The live-cell setup was performed at 37°C with 5% CO<sub>2</sub>.

## 2.9. *In vitro* methods

### 2.9.1. Protein purification

M27-RNaseH1-D210N (phospho-WT, S3xA and S3xD) fused with a His-MBP-3C tag was expressed in BL21 (DE3) *E. coli* cells using 0.5 mM IPTG at 18°C overnight in LB. Lysis was performed using sonication in IMAC buffer with 500 mM NaCl. First round of purification was performed on a HisTrap, followed by 3C protease digest overnight, heparin column purification to remove nucleic acids and concentration of the elution peak

using Amicon spin-concentrator. This was followed by gel filtration (Superdex 75 16/60 pg). Purified proteins were stored snap-frozen and stored at -80°C.

The HBD-AF647 was purified by the IMB Protein Purification. Detailed information on its design, purification and validation will be described in a PhD thesis by redacted (Petra Beli lab).

### 2.9.2. HeliX assay

Lyophilized single-stranded oligos (Oligo 1: ligand strand + target sequence; Oligo 2: overhang RNA or DNA complement) were resuspended in the Duplex buffer (IDT) at 100 µM. Oligo 1 and 2 were annealed (=conjugated ligand strand) in equimolar amounts (500 nM final) by mixing for 2 min at 94°C and then cooling at RT. Equal volumes of the 500-nM conjugated ligand strand and 400-nM Adapter strand 1-Ra were mixed and incubated for 20 min at RT at 600 rpm in the dark. Next, pre-incubated ligand-adapter mix was further mixed with an equal volume of Adapter strand 2-lfs. Serial dilutions (1/4) of 500 nM dCat M27-RNaseH1 (phospho-WT, S3xA, S3xD) were prepared in HE200 buffer on ice. The heliX device was supplied with reagents as described by the manufacturer (regeneration, passivation, test & standby solution, TE40 buffer, running buffer: HE200, biochip). Samples were run in a randomized order for each replicate, with chip regeneration between each dilution series.  $K_D$  values were calculated using continuous amplitude kinetics (real-time referencing + first blank).

## 2.10. Proteomics methods

### 2.10.1. Phosphoproteomics

One 10-cm plate was used per treatment. Until acetone precipitation, all steps were performed at 4°C. Cells were collected by washing twice with ice-cold PBS and lysing in RIPA supplemented with protease and phosphatase inhibitors. Lysates were incubated for 15 min, then 5M NaCl was added (1:10 V:V). Cells were sonicated using the Bioruptor Plus (7 cycles, 30s burst, 30s rest, high intensity) to enable chromatin extraction. Lysates were centrifuged for 15 min at 16 000 xg and supernatant concentrations measured using the Bradford assay. Lysates were purified by adding acetone in excess (80% volume)

overnight at  $-20^{\circ}\text{C}$ . All subsequent steps were performed at RT. Samples were pelleted at 1000 xg for 5 min and pellets dried on air. They were resolved in the urea:thiourea solution. Samples were reduced with 1 mM DTT for 45 min and alkylated using 5.5 mM chloroacetamide for 30 min. Proteins were digested using 1:50 (w:w) MS-grade trypsin (Serva) overnight at RT. Samples were incubated in TFA (0.5% V/V) for 1 h at  $4^{\circ}\text{C}$  and centrifuged for 10 min at 4,000 g. Peptide supernatants were purified using C18 Sep-Pak columns (Waters), eluted in 50% acetonitrile and dried using SpeedVac. Samples were barcoded with 0.1  $\mu\text{g}$  of acetonitrile-dissolved TMTPro or TMT11plex labels (Thermo Scientific) for 1 h and quenched with 5% hydroxylamine for 15 min<sup>225</sup>. An equal aliquot (5% vol) of each sample was mixed and the ratio check was performed as described<sup>226</sup>. After the ratio check, masses were adjusted treatment-wise. Samples were diluted with 0.1% TFA to reach  $< 3\%$  ACN and purified on SepPak columns, eluted with 50% ACN and acidified with 6% TFA. Phosphopeptides were enriched using titanium dioxide resin as described<sup>227</sup>. Samples were fractionated using either micro-SCX or high-pH reversed phase chromatography (Thermo Fisher) using manufacturer's instructions. Samples were mixed together and desalted using reversed-phase C18 StageTips<sup>228</sup>.

### 2.10.2. GFP-based interactomics

One 15-cm plate was used per treatment. HCT116:M27-RNaseH-GFP (phospho-WT or mutant) cells were treated for 24h with Dox and 1h with L41. DMSO was used as a mock treatment. Pulldowns were performed as described in "GFP-based pulldowns". After boiling in 2x LDS supplemented with 2 mM DTT, samples were alkylated with 10 mM chloroacetamide for 30 min in the dark at RT. To remove detergents, proteins were purified on SP3 beads<sup>229</sup>. Briefly, hydrophilic and hydrophobic Sera-Mag magnetic carboxylate modified particles (Sigma) were combined 1:1 (v:v), washed in water and resuspended in water at 20 mg/ml. 20  $\mu\text{l}$  of combined beads were added to each sample. Absolute ethanol was added to 50% (v/v) and samples were shaken for 5 min at 1000 rpm. After magnet binding, supernatants were removed and the beads were washed three times with 80% ethanol. Proteins were digested on-bead in the digestion buffer (150 mM HEPES, pH 8) with 0.5  $\mu\text{g}$  of MS-approved trypsin (Serva) per sample overnight at  $37^{\circ}\text{C}$  with shaking. After magnet binding, the supernatants were collected, and the beads were washed twice with the digestion buffer. Wash supernatants were combined with

respective peptide supernatants. Digestion was stopped by adding formic acid (FA) to 1%, and precipitates were removed by centrifugation after a 30 min incubation at 4°C. Samples were spun down for 10 min at 4000 xg and purified using StageTips.

### 2.10.3. FLAG-based interactomics

For SILAC labeling, cells were cultured for at least 5 passages in SILAC DMEM (Invitrogen) supplemented with dialyzed FBS (Invitrogen) and containing either L-arginine and L-lysine (Merck) or L-arginine [<sup>13</sup>C6] and L-lysine [<sup>2</sup>H4] (Cambridge Isotope Laboratories). Three 15-cm plates were used per treatment. All steps until bead boiling were performed on ice. U2OS:RNaseH1-FLAG-APEX2 were washed 2x with ice-cold PBS and lysed with mRIPA supplemented with protease inhibitors. To release the chromatin fraction, 2 mM MgCl<sub>2</sub> and 1:500 SmNuclease (IMB Protein Production) were added and incubated for 1 h. NaCl was added (450 mM final) and samples were incubated for 15 min. No-salt RIPA was added to reduce NaCl concentration to 150 mM. Samples were centrifuged for 15 min at 16 000 xg and supernatant concentrations measured with Bradford assay. 40 µl of mRIPA-equilibrated FLAG-M2 affinity gel (Merck) were added to equal mass of each sample. Samples were incubated rotating for 1.5 h, then washed 3x with mRIPA. Elution was performed by boiling in 2x LDS supplemented with 1 mM DTT for 15 min at 75°C. Alkylation was performed with 5.5 mM chloroacetamide for 45 min in the dark. Samples were separated by SDS-PAGE on a 4–12% gradient Bis–Tris gel (Invitrogen). Proteins were stained using the Colloidal Blue Staining Kit (Life Technologies) and digested in-gel using 0.6 µg of MS-approved trypsin (Serva) per gel fraction. Peptides were extracted from the gel and desalted using reversed-phase C18 StageTips.

### 2.10.4. LC-MS/MS

Run parameters for the LC-MS/MS runs are listed in the *Table 8*. Raw data files were analyzed using MaxQuant<sup>230</sup>. Site localization probabilities were determined by MaxQuant using the post-translational modification scoring algorithm. Parent ion and MS2 spectra were searched against a reference proteome database containing human protein sequences obtained from UniProtKB using Andromeda search engine<sup>231</sup>. Spectra were searched with a mass tolerance of 6 p.p.m. in MS mode, 20 p.p.m. in HCD MS2 mode,

strict trypsin specificity, and allowing up to two miscleavages. Cysteine carbamidomethylation was searched as a fixed modification, whereas protein N-terminal acetylation, methionine oxidation, phosphorylation (STY; only for Phosphoproteomics), and N-ethylmaleimide modification of cysteines (mass difference to cysteine carbamidomethylation) were searched as variable modifications. The dataset was filtered based on posterior error probability (PEP) to arrive at a false discovery rate of below 1% estimated using a target-decoy approach<sup>232</sup>. GFP-based interactomics was analyzed using the MSFragger<sup>233</sup>.

## 2.11. Bioinformatics analysis

### 2.11.1. Statistical analysis of MS data

Statistical analysis and MS data visualization were performed using the RStudio software environment (version 2024.04.2). Potential contaminants, reverse hits, hits only identified by site and hits with no unique peptides were excluded from the analysis. Phospho-sites were filtered based on localization probability (>75%). Statistical significance was calculated using a moderated t-test (limma package)<sup>234</sup>.

### 2.11.2. Kinase predictions

Computational prediction of kinase activity based on phosphoproteomics was performed using one of the three methods. For Kinase-Substrate Enrichment Analysis, it was based on the KSEA algorithm<sup>235</sup> and the R implementation of KSEA App<sup>236</sup>. Kinase-substrate annotations were obtained from PhosphoSitePlus (PSP) and the NetworkKIN database<sup>237</sup>. The analysis was performed with a minimum NetworkKIN score of 5 for upregulated and downregulated phosphorylation sites with a p-value  $\leq 0.05$ . For Kinase Library<sup>7</sup> method, differential expression-based enrichment analysis was performed with a log<sub>2</sub>-fold change threshold of 0.3 and p-value threshold of 0.05. For the KEA2 method<sup>238</sup>, significantly enriched phospho-sites were used as input for the literature-based kinase-substrate library (phospho-site level).

### 2.11.3. Miscellaneous bioinformatics analysis

Gene Ontology (GO) enrichment analysis was done using ViSEAGO package<sup>239</sup>. Phospho-motif analysis was performed on significantly upregulated phospho-sites using iceLogo<sup>240</sup>. Multiple alignment of RNase H1 from different species was performed with Clustal Omega<sup>241</sup> using default parameters. Results were visualized using JalView<sup>242</sup> and colored according to Percentage Identity. Structure modeling was performed with AlphaFold3<sup>243</sup> and visualized using PyMol.

## Chapter 3

### Results

---

#### 3.1. Stratification of replication stress by severity

Replication stress (RS) affects dividing cells in complex ways. It leads to changes in replication timing, origin firing, nuclear architecture, chromatin and replication fork remodeling, and activates checkpoint signaling and DNA repair. Importantly, the extent to which these processes are modulated, and the precise functional outcomes<sup>244</sup>, depend on RS severity. Traditionally, strong treatments were used to investigate cellular responses to RS, as these treatments elicited easily discernible phenotypes and led to massive changes in signaling. Recently, mild RS has emerged as a new candidate of intense study. This was triggered by the following observations: (1) mild RS allows progress through the cell cycle, enabling long-term accumulation of phenotypical consequences such as mutations<sup>85</sup>; (2) by allowing entry into G2 phase and mitosis, mild RS allows cell cycle-specific pathways, such as post-replicative repair<sup>245</sup> or mitotic DNA synthesis (MiDAS)<sup>246</sup>, to take place; (3) mild RS slows down replication forks, while strong RS blocks them, leading to different fork remodeling outcomes<sup>247</sup>; (4) endogenous RS that cells experience as a result of oncogene induction or replication over difficult-to-replicate regions is considered mild in nature<sup>248</sup>; (5) mild RS leads to both numerical and structural changes of chromosomes (chromosome instability or CIN)<sup>81</sup>; (6) mutations and CIN experienced by untransformed somatic cells as a result of mild RS are thought to be tumor-promoting<sup>249</sup>. Therefore, an improved understanding of cellular responses to mild RS is critical for a better understanding of tumorigenesis and improvement of therapeutic outcomes<sup>250</sup>. With this in mind, we set out to study global phosphorylation signaling upon different levels of RS.

As the first step, we stratified RS by severity using multiple phenotypic readouts. To modulate RS levels, we used a naturally occurring organic compound and B-family DNA polymerase inhibitor aphidicolin (APH). As the experimental system of choice, we used

the chromosomally stable colorectal tumor cells HCT116. These are often utilized to study MiDAS and the induction of CIN upon RS<sup>251,252</sup>. We use them throughout the study, unless specified otherwise. Treating cells acutely with increasing doses of APH led to a stepwise decrease in the replication fork progression rate, as measured by the DNA fiber assay (Figure 5A). Likewise, replication and DNA damage checkpoint signaling, measured by the activation of ATR-pCHK1 and ATM-pCHK2 pathways, was triggered in a dose- and time-dependent manner upon APH treatment (Figure 5B). Increased phosphorylation of the histone variant H2AX at S139 (commonly referred to as  $\gamma$ H2AX), an early event upon DSB induction and perhaps the most common marker of increased RS and DNA damage, was used as an additional readout. Finally, we investigated the influence of chronic APH treatment (24 h) on the cell cycle profile (Figure 5C). Interestingly, each of the applied RS doses led to a markedly different cell cycle profile. 100 nM APH, the lowest dose tested, caused a mild increase in the early S-phase population, but otherwise did not affect the cell cycle significantly. 400 nM APH, the medium dose, led to an accumulation of cells in G2 phase, likely because it allows replication, albeit at a much slower rate. 1000 nM APH, the strongest dose tested, caused a broad accumulation across S and G2 phase, likely as a result of the inability of early S-phase cells to finish replication, and delayed entry of late S-phase cells into G2. Altogether, these phenotypes allowed us to stratify RS into mild (100 nM APH), moderate (400 nM APH) and strong (1000 nM APH) RS (Figure 5D).

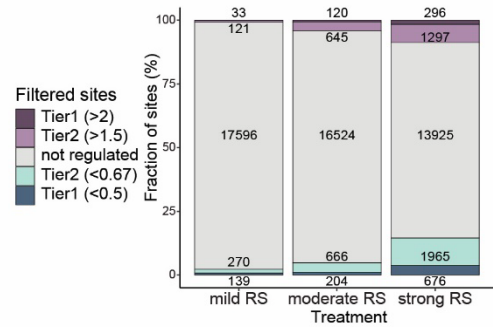

**Figure 5: Stratification of replication stress by severity.**

**A)** DNA fiber assay representing combined CldU and IdU track length. Both 30 min pulses and a 30 min pre-treatment were performed with indicated treatments in HCT116. **B)** Western blot analysis of HCT116 lysates treated for 4h or 24h with indicated APH concentrations. Vinculin is used as a loading control. **C)** Flow cytometry histogram after a 24h treatment of HCT116 with indicated APH concentrations. PI = propidium iodide. DNA content is in arbitrary units. **D)** A scheme of replication stress stratified by severity.

### **3.2. Phosphoproteomics of the dose-dependent response to replication stress**

Previous phosphoproteomics studies have focused on the replication stress (RS) levels that strongly activate the checkpoint and do not allow the entry of cells into mitosis<sup>253</sup>. However, it is currently unknown to which extent the various phosphorylation-mediated signaling pathways are induced or inactivated upon lower doses of RS. To study the signaling events associated with different RS levels, we performed multiplexed mass spectrometry-based quantitative phosphoproteomics after a 24-h treatment with the benchmarked RS levels in HCT116 (Figure 6A, left). In this experiment, we identified more than 18 000 high-quality phospho-sites (Figure 6A, right). As expected, the number of consistently regulated phospho-sites rose with the RS dose (Figure 6B). Importantly, mild RS led to an increase of 154 phospho-sites and a decrease of 409 sites (Tier 2 sites, fold change >1.5 and FDR < 0.05). This demonstrates that mild RS is sufficient to induce changes in signaling, despite not causing a strong induction of the checkpoint (Figure 5B), nor a large perturbation in the cell cycle profile (Figure 5C). Notably, some of the changes in phosphorylation upon mild RS might be due to a slight accumulation of cells in early S phase.

GO terms analysis of the proteins with a significant gain of phosphorylation upon different RS levels revealed that mild RS was linked with biological processes such as “DNA replication” and “histone demethylation” (Figure 6C). This strengthened the notion that studying global phosphorylation upon mild perturbations offers valuable insights into changes in replication dynamics. Proteins with a phosphorylation loss after mild RS mapped to GO terms associated with RNA processing, such as “RNA splicing”. Consistent with the cell cycle profile (Figure 5C), GO terms analysis of the phospho-sites gained upon moderate RS indicated the G2/M cell cycle arrest (Figure 6D). Phospho-sites gained upon strong RS were enriched for processes associated with DSB repair, in line with strong induction of the DSB markers  $\gamma$ H2AX and phospho-CHK2 (Figure 5B). As moderate and strong RS led to considerable perturbation of the cell cycle (Figure 5C), we expect that some phospho-sites regulated after these treatments represent genuine response to RS, whereas other sites simply reflect changes in the cell cycle profile.

**A)** (Left) Experimental outline of TMT phosphoproteomics after RS induction. (Right) Number of high-quality phosphorylation sites after filtering. **B)** High-quality sites categorized into up-, down- or non-regulated based on the fold change and false discovery rate (FDR < 0.05). **C)** GO biological processes of sites regulated after mild RS (ViseaGO package). **D)** GO biological processes of upregulated sites after moderate and strong RS (ViseaGO package). **E)** Volcano plot with sites significantly regulated after mild RS (Tier 2 sites). Sites mapping to GO-BP “DNA replication” are highlighted. **F)** Volcano plot with sites significantly regulated after moderate RS (Tier 1 sites). Sites mapping to GO-BP “DNA repair” are highlighted. **G)** Motif analysis of upregulated sites using iceLogo. **H)** Computational prediction of kinase activity using KSEA.

Analysis of individual phospho-sites affected by mild RS revealed increased phosphorylation of multiple DNA replication proteins (Figure 6E). This included the replicative helicase component MCM2, DNA polymerase  $\alpha$  subunit POLA2, single-strand break repair ligase LIG3, and origin firing factors CDC6 and Treslin (TICRR). Additionally, ribonucleotide reductase subunits RRM1 and RRM2 were affected, possibly reflecting changes in dNTP production rates upon RS. Among most strongly phosphorylated substrates after moderate RS were the cyclin-dependent kinases CDK1 and CDK2 at T14/Y15 (Figure 6F). These phosphorylation events inhibit CDK activity, and are strongly indicative of DNA damage-induced cell cycle arrest. Moreover, under moderate RS, phosphorylation of multiple DNA repair and fork stability proteins was apparent, such as of the Fanconi anemia pathway components FANCI and FANCE, DSB factors BRCA1 and MDC1, structure specific endonuclease SLX4, and DSB pathway choice regulators T53BP1 and RIF1 (Figure 6F). This opens up opportunities for further mechanistic study of these phosphorylation events.

Phosphorylation motif analysis showed enrichment of the S/T-Q motif after moderate and strong RS, indicating activation of the PIKK family of kinases, including the DSB kinase ATM and the RS response kinase ATR<sup>254</sup> (Figure 6G). Strong RS reduced phosphorylation at phospho-residues followed by a proline (P at +1 position), which we interpret as further indication of the CDK inhibition<sup>255</sup>. To investigate how the global kinase response is affected by different RS levels, we performed computational prediction of kinase activity using Kinase-Substrate Enrichment Analysis (KSEA) (Figure 6H). This

confirmed the stepwise activation of ATM and ATR, as well as a stepwise reduction of cell cycle-promoting CDKs and mitosis-promoting Aurora A/B and PLK1<sup>256</sup>. Interestingly, CDK1 was not predicted as downregulated after mild RS, potentially explaining the lack of cell cycle arrest in this condition.

### **3.3. Similarities in signaling between Cyclin E- and aphidicolin-induced mild replication stress**

Although aphidicolin and hydroxyurea are commonly used as tools to study RS, they are not the most physiological source of RS. Cancer-relevant RS occurs as a consequence of increased expression of oncogenes such as MYC, KRAS or Cyclin E<sup>89</sup>. An improved overview of the signaling induced by oncogenes would benefit our understanding of the pathways relevant for tumorigenesis. We therefore sought to compare APH- and Cyclin E1-induced phosphoproteomes. For this, we developed and made use of the U2OS cell line expressing the CCNE1 gene in a doxycycline-inducible manner (Figure 7A). TMT-based phosphoproteomics after a 24-h treatment with doxycycline (Figure 7B) revealed over 100 sites each that were either upregulated or downregulated upon CCNE1 overexpression (p-value <0.01). Phosphorylation of CCNE1 was strongly increased, acting as a positive control (Figure 7C). Y19 on CDK1/2/3 was more phosphorylated after CCNE1 induction, suggesting changes in CDK activity. Interestingly, APH and doxycycline treatment correlated very well (Pearson correlation coefficient = 0.61), revealing similarities in signaling (Figure 7D). The overlap was most noticeable among downregulated sites, which were enriched for RNA processing factors.

Kinase predictions after CCNE1 overexpression and APH-induced mild RS revealed further similarities at the signaling level (Figure 7E). While it was expected that Cyclin E increases CDK activity, in particular CDK2<sup>257</sup>, we observed a similar response after APH treatment. This suggests that after mild RS, CDK activity is in general not diminished, in line with the observation that cells do not get arrested in S or G2 (Figure 5C). Kinase prediction also retrieved plethora of potential kinases with less activity after RS, allowing further exploration.

**Figure 7: Similarities in signaling between Cyclin E- and aphidicolin-induced mild replication stress.**

and downregulated sites is indicated at the bottom. Selected sites are highlighted. **D)** Scatter plot comparing APH treatment and Cyclin E1 overexpression. RNA processing factors are highlighted. Pearson correlation coefficient is indicated. **E)** Scatter plot comparing kinase activity predictions using the Kinase Library after indicated treatments. Kinases predicted to be commonly regulated are highlighted.

### **3.4. Analysis of replication stress-induced changes in phosphorylation of R-loop regulators reveals regulation of RNase H1 and Senataxin by phosphorylation**

RS has a two-way relationship with R-loops. Namely, aberrant accumulation of R-loops increases RS, and vice versa. However, evidence for the latter is mostly based on the frequently criticized immunofluorescence using the S9.6 antibody<sup>217,258,259</sup>. To strengthen the notion that APH increases R-loop levels, we used a tool recently developed in our lab called the HBD-AF647 (Figure 8A). The tool utilizes purified hybrid binding domain of the human RNase H1 covalently linked to a fluorophore (Alexa Fluor 647), enabling fluorescent imaging of RNA:DNA hybrids and R-loops in fixed cells without the need for a secondary antibody (developed by redacted). Chronic RS (24 h), including mild RS, significantly increased the nuclear HBD-AF647 staining (Figure 8B). As expected, depletion of the RNA:DNA hybrid nuclease RNase H1, as well as the helicase AQR<sup>145</sup>, also considerably increased nuclear hybrid levels.

While a large number of R-loop-modulating helicases, nucleases, translocases and other R-loop binders have been characterized to date, their regulation by PTMs upon stresses that cause R-loop accumulation is just beginning to emerge<sup>260</sup>. To find out if R-loop factors are regulated by phosphorylation upon RS, we overlapped our phosphoproteomics data with a dataset of 186 high-confidence R-loop regulators reported in the R-loopBase<sup>261</sup> (Figure 8C). This revealed that phosphorylation of 36 R-loop regulators at 91 sites is significantly affected by at least one RS treatment (Figure 8D). Among them, we found multiple well-studied DDR proteins with R-loop-related and -unrelated functions, such as BRCA1 (13 sites), MDC1 (10 sites), FANCI (4 sites), FANCD2 (1 site), BLM (2 sites) and RPA1 (2 sites). We noticed that proteins with a loss of phosphorylation, such as HNRNPD, NPM1, NCL, DDX5, ADAR, SAFB2, PAF1 and NONO, were enriched for transcription-

and RNA processing-related functions (Figure 8D). Critically, we found increased phosphorylation of a bona fide R-loop helicase Senataxin/SETX<sup>125,262</sup> at 5 serine residues (S947, S950, T952, S956 and S1345), four of which are SQ sites, and decreased phosphorylation of one of the major R-loop nucleases RNase H1 at three serine residues (S74, S76 and S80). Interestingly, the reported phospho-serines on RNase H1 are located in an intrinsically disordered region immediately downstream of its hybrid-binding domain (HBD) (Figure 8E), prompting us to investigate their function.

Sequence comparisons from yeast to humans showed that HBD is universally followed by an array of phosphorylatable residues, most often serines, which we termed the phospho-cluster region (Figure 8F). Out of the three serines present in humans, S76 and S80 were the best conserved. Aiming to find the kinase phosphorylating RNase H1, we explored its interactome. To this end, we created a U2OS cell line with endogenously tagged RNase H1 fused with APEX and FLAG tags using CRISPR-Cas9. FLAG-based affinity purification coupled to LC-MS/MS revealed RNase H1 as the top hit (Figure 8G). In line with the role of RNase H1 in RNA processing, subunits of RNA Pol II<sup>263</sup>, the transcription elongation PAF1 complex, multiple histones and different R-loop-related DDX/DHX helicases were significantly enriched. Among enriched kinases, we found transcription- and splicing-related CDK11B and CDK12, as well as two subunits of the CK2 holoenzyme (CSNK2A1 and CSNK2B). S80 of RNase H1 is surrounded by three negatively charged residues (E78, E81 and E84) (Figure 8F), which resembles the motif necessary for hierarchical phosphorylation by CK2<sup>8</sup>, prompting us to investigate it as a candidate kinase. Phosphoproteomics upon chemical inhibition of CK2 using CX-4945<sup>264</sup> revealed that phosphorylation of RNase H1 at S74/S76 is strongly affected, even more so than after APH (Figure 8H). However, a closer inspection of the RS- and CX-4945-dependent substrates showed that two phospho-sites of another kinase, DYRK1A, are strongly affected by both treatments (Figure 8I). Additionally, a recent report highlighted DYRK1A as an off-target of CX-4945<sup>265</sup>.

### **3.5. Replication stress-mediated reduction in DYRK1A signaling leads to a loss of RNase H1 phosphorylation**

We therefore hypothesized that DYRK1A, rather than CK2, phosphorylates RNase H1. To facilitate the kinase search and further mechanistic exploration of RNase H1 phosphorylation, we developed two new tools. Using lentiviral transduction, we stably integrated a doxycycline (dox)-inducible construct bearing the GFP-tagged nuclear isoform of RNase H1, including the triple phospho-dead (S74A, S76A and S80A; abbreviated as S3xA) and the triple phospho-mimicking (S74D, S76D, S80D; abbreviated as S3xD) version into the HCT116 cell line (Figure 9A). Furthermore, we developed a custom phosphorylation-specific RNase H1 antibody raised against a peptide mono-phosphorylated at S74. Although the antibody displayed unspecific, knockdown-resistant bands at 30 kDa in inputs and pulldowns of endogenous RNase H1 (not shown), the phosphorylation was readily detectable in GFP-based pulldowns using the dox-inducible RNase H1 cell line (Figure 9B). Critically, the phospho-S74 signal was dox-dependent, and not visible upon expression of the S3xA nor the S3xD mutant of RNase H1, indicating that the antibody indeed recognizes the phospho-group on one of the three serines of

**A****B****C****D****E****F**

interest. The antibody-based approach confirmed that RS decreases phosphorylation of RNase H1 in a dose-dependent manner, while total levels of GFP-tagged RNase H1 remain unchanged (Figure 9C,D).

Strikingly, inhibition of DYRK1A using three different chemical inhibitors (Leucettine L41<sup>266</sup>, INDY<sup>267</sup> and harmine<sup>268</sup>), as well as CX-4945, almost completely reversed phosphorylation at S74, while depletion of DYRK1A using siRNA reduced it (Figure 9E). Additionally, total levels of DYRK1A decreased with the RS dose, offering an explanation for reduced phosphorylation of RNase H1 upon RS (Figure 9F).

### **3.6. Reduction in DYRK1A signaling is a driver of the replication stress-induced phosphorylation loss on RNA processing factors**

Assuming RNase H1 is not the only RS-regulated DYRK1A target, we next asked whether its other substrates are decreased in phosphorylation upon RS. To this end, we performed phosphoproteomics after strong RS, chemical inhibition of DYRK1A using L41 or INDY, or depletion of DYRK1A (Figure 10A). Principal component analysis (PCA) showed a clustering of the DYRK1A inhibitors, and their similarity with depletion of DYRK1A (Figure 10B). As expected, APH treatment displayed a distinct response. Pairwise comparison of the strong RS with either INDY or L41 revealed a subset of shared substrates (Figure 10C,D). Critically, both RS and inhibition of DYRK1A led to a reduction of its auto-phosphorylated activity-promoting residue S529<sup>269</sup>, strengthening the observation that RS

reduces DYRK1A signaling. Overlapping the downregulated phospho-sites dependent on RS, INDY and L41 revealed a subset of 27 substrates (Figure 10E). Among them were proteins like the DHX/DDX family RNA helicases DHX38 and DDX21, spliceosome B factor SF3B1 and alternative splicing factors RBMX and SAFB (Figure 10F). Kinase prediction using KEA2 confirmed that DYRK1A activity is reduced both after RS and DYRK1A inhibition (Figure 10G). In addition, it revealed pathways common to DYRK1A inhibitors, such as increased CDK2 and GSK3B activity, which merits further investigation. GO terms analysis revealed that targets with a loss of phosphorylation after DYRK1A inhibition or depletion are predominantly involved in RNA processing and splicing (Figure 10H). Finally, by overlapping sites regulated after DYRK1A inhibition or depletion, we generated a high-confidence set of DYRK1A targets (Figure 10I). Altogether, our results suggest that the reduction in DYRK1A signaling is one of the drivers of the previously observed loss of phosphorylation of RNA processing factors upon RS.

### **3.7. Functional implications of RNase H1 phosphorylation**

We hypothesized that DYRK1A-mediated phosphorylation of RNase H1 could impact its biological role in the following ways: it could change the propensity of the HBD to bind RNA:DNA hybrids, change RNase H1 localization, chromatin binding, activity, localization, or protein-protein interactions. To test the first hypothesis, we turned to *in vitro* nucleic acid-protein binding assays (Figure 11A). To this end, we purified phospho-WT or phospho-substituent catalytically inactive (D210N) RNase H1 lacking the mitochondrial localization signal (Figure 11B). Using surface plasmon resonance and a 12-mer RNA:DNA hybrid substrate, we showed that the S3xD mutant has a dissociation constant ( $K_D$ ) 1.8-fold higher than either WT or S3xA mutant, suggesting decreased hybrid binding (Figure 11C). Closer inspection of the binding dynamics revealed that S3xD associates with hybrids less efficiently, but is more prone to being retained on the hybrid upon washout (Figure 11D). As a specificity control, we compared binding of RNase H1 to dsDNA, confirming that RNase H1 binds to hybrids with much higher efficiency than to

dsDNA. Interestingly, S3xD also showed reduced binding to dsDNA, likely because RNase H1 binds dsDNA and hybrids in a similar way. Next, we used a live-cell fluorescent microscopy approach to investigate cellular localization of the phospho-mutants. While phospho-WT displayed an overall similar nuclear distribution to S3xA and S3xD, we noticed that the S3xA mutant displays a clear separation between the nucleolar and nucleoplasmic compartments, whereas this separation is impaired in the S3xD mutant (Figure 11E). This was further substantiated by the quantification of the coefficient of variation (CV) of nuclear intensity (Figure 11F), a measure which was previously used to study the impact of phosphorylation on protein distribution in the nuclear sub-compartments<sup>270</sup>. The S3xD mutant had a significantly reduced CV% in comparison to the S3xA, with WT being in between, likely because it is a mixture of the non-phosphorylated and phosphorylated species.

To test the impact of phosphorylation on chromatin levels, we monitored the amount of RNase H1 on chromatin and in the soluble fraction throughout a timecourse of a strong RS treatment (Figure 11G). While the chromatin levels of RNase H1 did not change throughout the timecourse, the levels of soluble RNase H1 slightly decreased at later timepoints, particularly at 24 h. This was preceded by the appearance of a faint higher-molecular weight band, possibly corresponding to ubiquitylated RNase H1. Therefore, we concluded that phosphorylation of RNase H1 does not influence the total levels of RNase H1 on chromatin, but it might be involved in the regulation of its stability.

## **3.8. Analysis of the phosphorylation-based changes in the RNase H1 interactome reveals a role of GSK3B in RNase H1 stability**

To investigate the possibility that phosphorylation of RNase H1 changes its interaction profile, we performed the LC/MS-MS-based interactome analysis after GFP-based pulldowns in HCT116 cells expressing WT or mutant RNase H1 (Figure 12A). Additionally, we treated WT-expressing cells with L41 to trigger the loss of phosphorylation. As expected, RNase H1 was by far the most enriched hit after doxycycline induction in WT cells (Figure 12B). Pairwise comparisons of S3xA-expressing cells and L41-treated cells revealed factors with a preference for binding either phosphorylated or non-phosphorylated RNase H1 (Figure 12C). Multiple interactors were RNA-binding proteins known to reside in the nucleoli, mirroring nucleolar localization of RNase H1. Among them, nucleolin (NCL), FUS and SFPQ preferentially interacted with non-phosphorylated RNase H1. These proteins are involved in condensate formation (phase separation), potentially explaining our observation that S3xA mutant has a better nucleolar-nucleoplasmic separation than S3xD. On the other hand, phosphorylated RNase H1 interacted with a subunit of the rDNA-transcribing RNA Pol I subunit POLR1F and, in

addition, with two factors involved nucleolar transcription at rDNA and its intergenic spacers (IGSs), TOP1<sup>271</sup> and RAD51C<sup>272</sup>. Additionally, among the hits with a preference for phosphorylated RNase H1 was the PRMT5 arginine methyltransferase complex, including the catalytic subunit PRMT5, the non-catalytic component WDR77 and the substrate adaptor RIOK1. This suggests RNase H1 might be methylated in a phosphorylation-dependent manner.

Treatment with L41 led to a strong loss of interaction of RNase H1 with the GSK3 $\beta$  kinase (Figure 12D). This caught our interest, as GSK3 $\beta$  is known to phosphorylate substrates primed by DYRK1A<sup>31</sup>. GSK3 $\beta$ -mediated phosphorylation often introduces a phospho-degron, enabling substrate ubiquitylation by the SCF ubiquitin ligase and subsequent degradation by the proteasome<sup>28</sup>. In line with this, the S3xA mutant showed decreased binding to multiple proteasome subunits (Figure 12E), and had higher overall expression levels than WT (Figure 9A), indicating a potential defect in its ubiquitin-mediated degradation. S3xD mutant interacted with the phospho-degron reader FBXL6 (Figure 12F), which acts together with the SCF ligase<sup>273</sup>, offering a possible candidate linking the RNase H1 phospho-cluster with the SCF.

To test if GSK3 $\beta$  regulates total levels of RNase H1, we treated HCT116 cells with a selective GSK3 $\beta$  inhibitor CHIR99021<sup>274</sup>. Prolonged treatment with CHIR99021 led to a strong increase in total levels of RNase H1, and a concomitant increase in pS74 (Figure 12G). This confirmed that GSK3 $\beta$  regulates levels of RNase H1 and that DYRK1A, rather than GSK3 $\beta$ , phosphorylates pS74. To exclude cell type-specific or inhibitor off-target effects, we used mouse embryonic fibroblasts (MEFs) with a biallelic knockout (KO) of GSK3 $\alpha$ <sup>275</sup> or GSK3 $\beta$ <sup>276</sup>. While GSK3 $\alpha$  KO did not have an effect on RNase H1 stability, GSK3 $\beta$  KO led to a 1.5-fold increase in total levels of RNase H1 (Figure 12H,I). In summary, our results suggest that phosphorylation of RNase H1 affects its interaction landscape and might thus regulate its localization or methylation. Additionally, we find strong evidence that DYRK1A-mediated phosphorylation of RNase H1 serves to recruit GSK3 $\beta$ , which could introduce a phospho-degron and therefore induce proteasomal degradation of RNase H1.

## Chapter 4

---

### Discussion

---

#### 4.1. Relationship between replication stress and the cell cycle

Our efforts to stratify RS by severity revealed major cell cycle differences between the RS treatments in HCT116 (Figure 5C). For example, while mild RS did not significantly affect the cell cycle, moderate RS caused a shift towards the G2 phase, and strong RS towards the S phase. It would be interesting to explore whether longer treatments with mild RS eventually stall the cell cycle, considering that DNA repair processes are carried over into the subsequent stages of the cell cycle (G2 in case of post-replicative gap filling<sup>277</sup>, mitosis in case of MiDAS<sup>246</sup>, or G1 in case of the post-mitotic DNA synthesis<sup>278</sup>). In particular, inheriting DNA lesions into the subsequent cell cycle increases duration of the G1 phase<sup>63</sup>.

Interestingly, live-cell imaging using the PCNA chromobody in U2OS cells revealed that treatment with moderate RS (400 nM APH) increases the duration of S phase from roughly 6 h to more than 24 h<sup>279</sup>. Therefore, the shift towards G2 after moderate RS can be explained, at least in part, by the severely prolonged duration of the S phase. In addition, multiple lines of evidence (Figure 5B,C; Figure 6D,F,H) suggest DNA damage checkpoint activation after moderate RS, likely as a result of unrepaired DNA lesions. Considering that strong RS almost completely blocks the progression of the replication forks<sup>280</sup>, it is expected that cells are unable to finish the S phase. The cell cycle effects we observed are likely cell-type dependent, as each cell line has a unique cell cycle duration and sensitivity to RS can vary depending on the mutational landscape and the expression profile of the cell line.

The interpretation of the aphidicolin-induced changes in phosphorylation is complicated by the cell cycle effects. Therefore, to understand which events are a direct result of the RS, and which are purely cell-cycle driven, one would need to categorize significantly

changing sites after 24-h RS using the database of phosphorylation abundance changes across the cell cycle stages<sup>281</sup>.

## **4.2. Comparison of Cyclin E- and APH-induced signaling**

The cell cycle phase transitions are governed by the complexes of cyclins and CDKs<sup>282</sup>. In complex with CDK2, Cyclin E promotes the G1/S transition, which is premature if Cyclin E is amplified, leading to replication stress induction<sup>47</sup>. Comparison of different sources of RS revealed that APH unexpectedly mimics Cyclin E induction at the signaling level. Namely, phosphorylation of Cyclin E itself was increased after both Cyclin E induction and APH. Two of the commonly increased phospho-sites (T352, corresponding to T395 on the canonical CCNE1 isoform; and S344, corresponding to S387 on the canonical CCNE1 isoform) are CDK2 targets<sup>283</sup>. This is significant for two reasons. Firstly, it validates the expected increase in CDK2 activity after Cyclin E induction, which is further evidenced by the kinase predictions (Figure 7E). Secondly, it implies that CDK2 activity is also elevated after APH treatment. Of note, CDKs have similar phosphorylation motifs and overlapping sets of targets<sup>284</sup>, making it difficult to tell them apart in kinase prediction approaches. Moreover, CCNE1 was also shown to bind to and activate CDK1<sup>285</sup>. Thus, our results provide further evidence that CDK activity is elevated, rather than inhibited, after mild RS. This is significant as CDK1 has been reported as the driver of increased origin firing after mild RS<sup>252,286</sup>.

It is important to note that the comparison between CCNE1- and APH-induced RS was performed in the U2OS background, while other experiments were performed in HCT116. We noticed that U2OS cells were less overall less affected by RS than HCT116 cells, which might stem from their different sensitivities to RS.

## **4.3. RNase H1 interactome reveals transcription- and RNA processing-related roles**

Despite the ubiquitous use of RNase H1 as a tool in R-loop biology, relatively little is known about how its function in human cells is determined by its interactors. Our

interaction profiling of RNase H1 revealed that it is largely associated with the transcription machinery and RNA processing factors (Figure 8G). For example, we have detected three RNA Pol II subunits (POLR2A, POLR2C and POLR2H) interacting with RNase H1. This suggests RNase H1 might have a co-transcriptional hybrid removal activity aided by interactions with core transcription components. This is supported by recent reports of RNase H1 phase-separating into Pol II transcriptional condensates<sup>263</sup>. Therefore, we speculate that the separation in RNase H1 and H2 functions might be determined by the fact that RNase H1 is associated with transcription machinery, while RNase H2 associates with the replication machinery<sup>161</sup>. RNase H1 also interacted with three subunits of the transcription elongation PAF1 complex, PAF1, CTR9 and LEO1 (Figure 8G). Interestingly, depletion of the components of the PAF1 complex leads to accumulation of R-loops<sup>177</sup>. We suggest testing whether the ability of the PAF1 complex to suppress R-loops, at least in part, depends on RNase H1.

#### **4.4. Unresolved questions about the phosphorylation of RNase H1**

Our phosphoproteomics results suggest that RNase H1 is less phosphorylated on all three serine residues (S74, S76 and S80) after RS (Figure 8D). However, it was so far difficult to discern whether semi-phosphorylated intermediates exist, or whether RNase H1 is either non-phosphorylated or triple-phosphorylated. Considering that, unlike S74 and S76, phosphorylation at S80 has not been reported on PhosphoSitePlus, this suggests it might be a rarer event that happens sub-stoichiometrically in comparison to phosphorylation at S74 and S76. One possibility is that phosphorylation at S80 introduces a phospho-degron, which will be discussed below. This would explain why it is more difficult to detect. In that case, treatment with proteasome inhibitors, such as MG132, should stabilize such phosphorylation and enable its easier detection, which we plan to test. Experiments with CX-4945 showed that DYRK1A might phosphorylate both S74 and S76 (Figure 8H). We consider this likely for the following reason. Although we have convincingly shown S74 is the substrate of DYRK1A, S76 better fits its consensus phosphorylation motif. Namely, DYRK1A has a preference for positively charged residues ahead of the serine/threonine,

particularly for arginine (R) at -3, and for proline (P) at +1<sup>287</sup>. The amino acid environment of S76 thus slightly better supports its phosphorylation (VRKS<sub>74</sub>AS<sub>76</sub>PEVS<sub>80</sub>). An additional aspect is the phosphorylation occupancy, which can be tested in stringent pulldowns of GFP-tagged RNase H1<sup>288</sup>. Including inhibitor treatments in this setup will hopefully enable discerning the contribution of DYRK1A and GSK3 $\beta$  to phosphorylation of the three residues of interest. This can be further confirmed by *in vitro* kinase assays.

While our initial phosphoproteomics results do not distinguish the two isoforms (Figure 8D), the results using the M27-RNase H1-GFP suggest that DYRK1A phosphorylates the nuclear isoform (Figure 9C). Since DYRK1A was also found to phosphorylate mitochondrial proteins<sup>289</sup>, it is possible that it acts on mitochondrial RNase H1 in a similar way. Alternatively, if RNase H1 is phosphorylated in the mitochondria or the cytoplasm, this could be mediated by another kinase.

## 4.5. Functions of RNase H1 phosphorylation

Our functional analyses suggest that phosphorylation of RNase H1 might regulate multiple biological roles, and that there might indeed be functional differences between semi- or fully-phosphorylated RNase H1. While we have started studying the effects of phosphorylation on hybrid binding, this should be further expanded. For example, we have so far shown that the S3xD mutant has reduced binding to hybrids in comparison to the S3xA mutant (Figure 11C,D). However, it is not clear whether S3xD functionally mimics phosphorylation of RNase H1. Therefore, another approach would be to test binding to hybrids upon *in vitro* phosphorylation using purified DYRK1A and phospho-WT or S3xA dCat RNase H1. Furthermore, the impact of phosphorylation on R-loop/hybrid degradation should be tested *in vitro*<sup>212</sup> and *in vivo*. To test this *in vivo*, we are planning to perform immunofluorescence experiments using the RHINO probe<sup>116</sup>, as well as genomic mapping of R-loops using MapR<sup>223</sup>.

Previous research had demonstrated that the HBD is critical for the nucleolar localization of RNase H1<sup>197</sup>. Our results demonstrate that the phospho-cluster regulates the degree of nucleolar-nucleoplasmic separation, likely either through interactions of RNase H1 with nucleic acid species, or with other proteins. This should be further tested, using treatments

expected to perturb RNase H1 phosphorylation, such as APH or DYRK1Ai. Considering that APH treatment reduces phosphorylation at all 3 serine residues (Figure 8D), we expect it would behave similarly like the S3xA mutant, although the effects would likely not be as striking. Treatment with DYRK1Ai would be less straightforward to interpret, as we are not sure it would perturb phosphorylation of all three serines. On the other hand, we are not sure if phosphorylation on all 3 sites is necessary for the change in localization. This could be tested by expressing GFP-tagged semi-phosphorylated phospho-mutants of RNase H1.

#### **4.6. DYRK1A – a new R-loop regulator?**

The phosphoproteome we performed after inhibition or depletion of DYRK1A offers valuable insights into DYRK1A signaling. For example, kinase prediction analysis revealed that DYRK1A inhibition increases activity of GSK3 $\beta$  and CDK2. Critically, DYRK1A inhibits GSK3 $\beta$  by phosphorylation at T356<sup>290</sup>, providing an explanation for why GSK3 $\beta$  activity would be elevated upon DYRK1A inhibition. That CDK2 activity is increased is in agreement with previous phosphoproteomics experiments<sup>287</sup>. Mechanistically, DYRK1A inhibition might boost CDK activity by promoting the accumulation of cyclins<sup>291</sup>. Therefore, our results suggest that an increase in CDK activity observed after APH-induced mild RS (Figure 7E) might be due to lower DYRK1A activity (Figure 9F). This could be tested by overexpressing DYRK1A under conditions of mild RS and measuring CDK activity.

Although we did not manage to quantify sites on RNase H1 in the DYRK1Ai phosphoproteomics (Figure 10), likely due to the nature of data-dependent acquisition<sup>292</sup>, we found a loss of phosphorylation at a double-phosphorylated RNase H1 peptide (S74/S76) upon chemical inhibition of DYRK1A in a previously published phosphoproteome<sup>287</sup>.

Considering the intimate relationship between transcription, RNA processing and R-loop levels, as well as the large number of RNA processing factors affected by inhibition of DYRK1A, we speculate that it might have a role in R-loop homeostasis. For example, we found that inhibition of DYRK1A lowers phosphorylation of the DDX/DHX-box proteins

DDX21 and DHX38 (Figure 10F), which have been associated with R-loop resolution<sup>151,293</sup>. This role might be disease-relevant, considering that DYRK1A imbalance is implicated in neurological disorders and cancer<sup>10</sup>. Interestingly, Down syndrome is characterized by early-onset hematological cancers<sup>294</sup>, which often occur due to R-loop mis-regulation<sup>90,153,154,181</sup>. Moreover, dose imbalance of DYRK1A in Down syndrome is associated with premature aging and unrepaired DNA damage<sup>295</sup>, phenotypes that R-loops could also contribute to. We therefore plan to test R-loop levels after DYRK1A depletion or inhibition.

#### **4.7. GSK3 $\beta$ – stabilization of RNase H1 through a ubiquitin-dependent mechanism?**

The interactome of RNase H1 revealed that it interacts with GSK3 $\beta$  in a DYRK1A-dependent manner (Figure 12D). Based on this, we hypothesized that DYRK1A primes RNase H1 for GSK3 $\beta$ -mediated phosphorylation, as has previously been demonstrated for multiple substrates<sup>32</sup>. Although we did not experimentally test this, we find it likely that GSK3 $\beta$  would phosphorylate S80 of pre-phosphorylated RNase H1. Using AlphaFold3, we modeled GSK3 $\beta$  interaction with an RNase H1 peptide pre-phosphorylated at S74 and S76 (Figure 13A). The model with the highest iPTM score (0.8) showed an interaction of the GSK3 $\beta$  positively charged pocket, comprised of the residues R96, R180 and K205, with pS74 of RNase H1 (Figure 13B). This pocket is known to bind phosphorylated residues on primed GSK3 $\beta$  substrates<sup>296</sup>. Interestingly, 4 out of 5 models predicted interaction of the positively charged pocket with pS74, while one showed the interaction with pS76. Only the interaction with pS74 would allow the ATP to be placed proximally to S80 of RNase H1, and thereby enable its phosphorylation (Figure 13C). It is important to note that GSK3 $\beta$  usually phosphorylates substrates primed downstream of the phosphosite, at the +4 position<sup>296</sup>. In the case of RNase H1, we predict GSK3 $\beta$  would bind the priming residue at the -6 position, which, if experimentally validated, would reveal a new class of GSK3 $\beta$  priming preferences.

We plan to further investigate the possibility that GSK3 $\beta$  introduces a phospho-degron into RNase H1. This will consist of testing whether: (1) S80 of RNase H1 is responsive to

GSK3 $\beta$  inhibition; (2) DYRK1A is necessary for GSK3 $\beta$ -mediated phosphorylation; (3) the S3xA mutant loses sensitivity to GSK3 $\beta$  inhibition for its stabilization; (4) RNase H1 is ubiquitylated in a manner dependent on GSK3 $\beta$ , a phospho-degron binder (eg. FBXL6 - Figure 12F), the SCF E3 ligase<sup>26</sup> and NEDD8<sup>297</sup>; (5) the S3xA mutant loses GSK3 $\beta$ -dependent ubiquitylation.

**Figure 13: Modeling the interaction of GSK3 $\beta$  with the RNase H1 phospho-cluster region.**

**A)** AlphaFold3-modeled interaction of the GSK3 $\beta$  with the double-phosphorylated (pS74-pS76) RNase H1 phosphopeptide rendered in PyMol. ATP and Mg<sup>2+</sup> ions are also shown. **B)** Zoomed-in view of RNase H1 pS74 interacting with the positively charged pocket of

GSK3 $\beta$ . **C)** Zoomed-in view of the active site of GSK3 $\beta$  occupied by ATP and Mg<sup>2+</sup> ions, positioned proximally to S80 of RNase H1.

## 4.8. Conclusions

Based on the presented results, we propose a model of regulation of RNase H1 phosphorylation and its function under replication stress (Figure 14A). In unchallenged conditions, RNase H1 is phosphorylated by DYRK1A at S74 (Figure 9E) and (likely) S76. DYRK1A also inhibits GSK3 $\beta$  activity by phosphorylating it at T356<sup>290</sup>. Under prolonged replication stress, DYRK1A levels are decreased (Figure 9F) and GSK3 $\beta$  is therefore activated. GSK3 $\beta$  then phosphorylates S80 of RNase H1 (Figure 12D,G-I; Figure 13), introducing a phospho-degron. The phosphorylated pool of RNase H1 is therefore degraded in a proteasome-dependent manner (Figure 12E). Because the non-phosphorylated pool is continuously synthesized, this increases its relative amount after replication stress (Figure 9C,D). Since non-phosphorylated version has a higher affinity towards RNA:DNA hybrids (Figure 11C,D), this should increase the degradation of R-loops. Importantly, this model does not require the activity of a phosphatase on RNase H1, as phosphorylation is lost through degradation. Alternatively, if effects of GSK3 $\beta$  on the levels of RNase H1 are more indirect, the loss of DYRK1A activity is sufficient to decrease the pool of phosphorylated RNase H1 upon replication stress.

We also propose that the semi-phosphorylated RNase H1 might affect the distribution of RNase H1 in the nucleoli and the nucleoplasm, its protein-protein interactions and the RNA:DNA hybrid binding (Figure 14B). Fully phosphorylated RNase H1 should, on the other hand, drive the degradation of RNase H1. The reader should keep in mind that parts of this model are preliminary and require further study.

**B**

**Functional effect**

Hybrid binding	Localization	Interactions	Degradation
S3xD binds to hybrids less than S3xA	Altered nucleoplasmic-nucleolar separation	<u>Phospho preference:</u> PRMT5, WDR77, RIOK1, GSK3β, TOP1, etc.	RS-induced decrease in soluble RH1 RS-induced appearance of high-Mw RH1
		<u>Non-phospho preference:</u> FUS, NCL, SFPQ, histones, etc.	DYRK1A triggers GSK3β binding to RH1 Stabilization of RH1 upon GSK3βi or KO
			S3xA expressed higher than WT
			Decreased proteasome binding of S3xA
			S3xD binds FBXL6

Evidence

**Figure 14: Model – regulation of RNase H1 by phosphorylation.**

**A)** DYRK1A-, RS- and GSK3β- mediated regulation of RNase H1 phosphorylation and stability. See section 4.8 for explanation. **B)** Proposed functions of RNase H1 phosphorylation and its loss. Evidence for each functional effect collected in this study is presented in the table.

## Chapter 5

### Appendix

---

#### 5.1 Abbreviations

AOA2	Type 2 ataxia with oculomotor apraxia
AGS	Aicardi–Goutières syndrome
AML	Acute myeloid leukemia
APH	Aphidicolin
AQR	Aquarius
ALS4	juvenile amyotrophic lateral sclerosis
ALT	Alternative telomere lengthening
ATM	Ataxia-telangiectasia mutated
ATP	Adenosine-5'-diphosphate
ATR	Ataxia telangiectasia and Rad3 related
BER	Base excision repair
BIR	Break-induced replication
bp	Base pair
BRCA	Breast cancer
BrdU	5-Bromo-2'-deoxyuridine
BSA	Bovine serum albumin
CDK	Cyclin-dependent kinase
CFS	Common fragile site

ChIP	Chromatin immunoprecipitation
CIN	Chromosome instability
CldU	5-Chloro-2'-deoxyuridine
CP	Core particle
CTD	C-terminal domain
DDK	Dbf4-dependent kinase
DDX	DEAD-box
DHX	DEAH-box
diIncRNA	DNA damage-induced long non-coding RNA
DMEM	Dulbecco's Modified Eagle Medium
DNA	Deoxyribonucleic acid
dNTP	Deoxynucleotide triphosphate
Dox	Doxycycline
DS	Down syndrome
DSB	Double-strand break
dsDNA	Double-stranded deoxyribonucleic acid
DTT	dithiothreitol
DUB	Deubiquitylating enzyme
DYRK	Dual-specificity tyrosine phosphorylation-regulated kinase
E1	Ubiquitin-activating enzyme
E2	Ubiquitin-conjugating enzyme
E3	Ubiquitin ligase
EDTA	Ethylenediaminetetraacetic acid

G4	G-quadruplex
GI	Genome instability
GSK3	Glycogen synthase kinase
HBD	Hybrid-binding domain
HSPC	Hematopoietic stem progenitor cell
HR	Homologous recombination
HU	Hydroxyurea
IdU	5-Iodo-2'-deoxyuridine
IF	Immunofluorescence
IGS	Intergenic spacer
lncRNA	Long non-coding RNA
MCM	Minichromosome maintenance protein complex
MDS	Myelodysplastic syndrome
MiDAS	Mitotic DNA synthesis
MLS	Mitochondrial localization signal
NELF	Negative elongation factor
NER	Nucleotide excision repair
NFAT	Nuclear factor of T cells
NLS	Nuclear localization signal
NHEJ	Non-homologous end joining
nt	Nucleotide
OF	Okazaki fragment
ORC	Origin recognition complex

p-TEFb	Positive transcription elongation factor
PARP	Poly (ADP-Ribose) Polymerase
PBS	Phosphate-buffered saline
PCNA	Proliferating cell nuclear antigen
PEI	Polyethyleneimine
PEO	Progressive external ophthalmoplegia
Phospho	Phosphorylation
PIC	Pre-initiation complex
PIKK	Phosphatidylinositol 3-kinase-related kinase
PIP-box	PCNA interacting protein-box
PRC2	Polycomb repressive complex 2
pre-RC	pre-Replication Complex
PRIMPOL	Primase and DNA directed polymerase
PTM	Post-translational modification
rDNA	Ribosomal DNA
RBR	RING-between-RING
RER	Ribonucleotide excision repair
RF	Replication fork
RNA	Ribonucleic acid
RNR	Ribonucleotide reductase
RNAPII / Pol II	RNA polymerase II
rNTP	Ribonucleotide triphosphate
ROS	Reactive oxygen species

RP	Regulatory particle
RPA	Replication protein A
RS	Replication stress
S-CIN	Structural chromosome instability
ssDNA	Single-stranded DNA
TC-NER	Transcription-coupled nucleotide excision repair
TERRA	Telomere repeat-containing RNA
TLS	Translesion synthesis
TOP1	Topoisomerase 1
TRC	Transcription-replication conflict
TS	Template switching
TSS	Transcription start site
UPS	Ubiquitin-proteasome system
W-CIN	Whole-chromosome instability
