## Summary

Pleiotropy describes a phenomenon in which two or more traits are controlled by a single genetic factor. Since several traits can be negatively associated with each other, resulting in trade-offs, studying pleiotropic gene functions is of great importance for understanding the evolution of plant metabolic traits and biotechnological optimization of plants. Using the giant duckweed *Spirodela polyrhiza* as a model organism for investigating pleiotropic gene functions in plants, this thesis aims to identify gene candidates controlling herbicide resistance, metabolite contents and sexual reproduction in *S. polyrhiza*. For this we quantified the intra-specific variation in free metabolite contents, growth and diquat resistance in *S. polyrhiza*. Candidate genes associated with these traits were identified through genome-wide association studies (GWAS). The first article focuses on quantifying the phenotypic variation in diquat resistance, revealing 8.5-fold differences between the most resistant and most susceptible genotypes. Genotypes showed variation in superoxide dismutase activity, ratios of oxidized to reduced antioxidant contents and uptake kinetics of diquat. On a genetic level, genes involved in biotic stress responses (*SpLOX2.1* and *SpGBPL2*), apoptosis control (*SpDLH*) and starch metabolism (*SpSBE3*) were associated with diquat resistance. The second article focuses on identifying candidate genes controlling variation in free metabolite contents and growth in *S. polyrhiza*. Overall, secondary metabolites showed stronger intra-specific variation than primary metabolites and growth parameters. Often primary metabolites showed strong correlations with plant biomass. A GWAS conducted on free metabolite levels identified candidate genes controlling photosynthesis (*SpLHCB5*), protein-degradation (*SpUBP7*), cell-cycle (*SpPUB4*) and secondary metabolite synthesis (*SpMYBC1*) to be associated with biomass-correlated traits. The third study investigates the migration history and genetic diversity of *S. polyrhiza*. Analysis of population structure revealed four genetic populations for this duckweed species, which were largely defined by their geographic locations as American, SE-Asian, Indian and European populations. A genome-wide scan identified 69 genes, whose homologs were mainly linked to sexual reproduction processes to be under selection. Together, this thesis studies gene candidates controlling herbicide resistance, free metabolite contents and sexual reproduction in *S. polyrhiza*, which can be used for biotechnological optimization of this plant. The results further suggest that pleiotropic genes involved in stress responses confer non-targeted site herbicide resistance.

## Zusammenfassung

Pleiotropie beschreibt die genetische Kontrolle einer oder mehrerer Eigenschaften durch einen einzigen genetischen Faktor. Hierdurch können negative Assoziation von Eigenschaften, sogenannte Trade-offs entstehen. Daher ist die Erforschung von pleiotropen Effekten von zentraler Bedeutung für evolutionäre Studien zum Thema pflanzlicher Metabolismus und für die biotechnologische Optimierung von Pflanzen. Die vorliegende Arbeit befasst sich mit der Beschreibung pleiotroper Gene im Modellorganismus *Spirodela polyrhiza*, wobei Genfunktionen im Zusammenhang mit Herbizidresistenz, sexueller Reproduktion und Metabolitkonzentrationen identifiziert werden sollen. Hierfür wurden intraspezifische Variationen von Metabolitkonzentration, Wachstumsrate und Diquatresistenz in Genotypen von *S. polyrhiza* bestimmt. Mit diesen Eigenschaften assoziierte Gene wurden mittels Genomweiter Assoziationsstudien (GWAS) identifiziert. Der erste Artikel dokumentiert Variationen von Diquatresistenz in *S. polyrhiza*, wobei der resistenteste Genotyp eine 8.5-fach höhere Resistenz gegenüber des niedrigsten Resistenzniveaus aufwies. Weiterhin unterschieden sich die Genotypen hinsichtlich antioxidativer Eigenschaften und ihrer Diquataufnahmekapazität. Auf genetischer Ebene konnten Gene im Zusammenhang mit biotischen Stressantworten (*SpLOX2.1* and *SpGBPL2*), Apoptose (*SpDLH*) und Stärkemetabolismus (*SpSBE3*) mit Diquatresistenz assoziiert werden. Der zweite Artikel befasst sich mit der Identifizierung von Genen, welche Wachstum und Metabolitkonzentrationen in *S. polyrhiza* kontrollieren. Insgesamt zeigten Sekundärmetabolite eine geringere intraspezifische Varianz als Primärmetabolite und Wachstumsparameter. Primärmetabolite waren oft stark mit pflanzlicher Biomasse korreliert. Mittels GWAS wurden Gene, welche Prozesse wie Photosynthese (*SpLHCB5*), Proteinabbau (*SpUBP7*), Zell-Zyklus (*SpPUB4*) oder Sekundärmetabolitsynthese (*SpMYBC1*) regulieren, mit Biomasse-korrelierten Eigenschaften assoziiert. Die dritte Studie ergründet die historische Migration und genetische Vielfalt von *S. polyrhiza*. Mittels demographischer Analyse wurden vier genetische Populationen, welche nach ihrem Verbreitungsgebiet als Amerika, SO-Asien, Indien und Europa – Populationen benannt wurden, identifiziert. Ein genomweiter Scan ergab, dass 69 Gene, welche überwiegend mit sexueller Reproduktion assoziiert waren, unter Selektion stehen. Zusammenfassend identifizierte diese Arbeit zahlreiche Gene mit Bezug zu Herbizidresistenz, Metabolitkonzentrationen und sexueller Reproduktionen, welche zur biotechnologischen Optimierung von *S. polyrhiza* genutzt werden können. Aufbauend darauf scheinen Gene, welche an Stressantworten beteiligt sind, non-targeted site Resistenz gegen Diquat zu vermitteln.

## List of Abbreviation

ABC – ATP-binding cassette  
AGL6 – AGAMOUS - LIKE 6  
AGL62 – AGAMOUS - LIKE 62  
AGO1 – ARGONAUT 1  
AOS – ALLENE OXIDE SYNTHASE  
AP3 – APETALA 3  
ATP – Adenosine-trisphosphate  
BB – BIG BROTHER  
BLINK – Bayesian-information and linkage-disequilibrium iteratively nested keyway  
cDNA – Complementary desoxyribonucleic acid  
CYP450 – CYTOCHROME P450  
DNA – Desoxyribonucleic acid  
DTH8 – DAYS TO HEADING 8  
EDDHA – Ethylenediamine-*N,N'*-bis(2-hydroxyphenylacetic acid)  
EDS1 – ENHANCED DISEASE SUSCEPTIBILITY 1  
FarmCPU – Fixed and random model circulating probability unification  
FLK – FLOWERING LOCUS K  
Fm – Maximum fluorescence  
Fm` – Maximum fluorescence (light adapted state)  
Fv – Variable fluorescence  
Fv` – Variable fluorescence (light adapted state)  
GLM – Generalized linear model  
GSH – Glutathione  
GWAS – Genome-wide association study  
HPLC-MS – High performance liquid chromatography – mass spectrometry  
IPA1 – IDEAL-PLANT ARCHITECTURE 1  
K<sub>a</sub> – Substitutions on non-synonymous sites  
K<sub>s</sub> – Substitutions on synonymous sites  
LC-MS – Liquid chromatography mass spectrometry  
MADS – MCM1 AGAMOUS DEFICIENS SRF  
MCM1 – MINI CHROMOSOME MAINTENANCE 1

MIKC<sup>C</sup> – MADS - intervening, keratin-like and C-like domain  
miR – microRNA  
MLM – Mixed linear model  
MLMM – Multi locus mixed model  
NLR – NUCLEOTIDE-BINDING LEUCINE-RICH REPEAT  
NPR1 – NONEXPRESSOR OF PATHOGENESIS-RELATED GENES 1  
NTSR – Non-targeted-site resistance  
PAL – PHENYLALANINE AMMONIA LYASE  
PCA – Principal component analysis  
pH – Pondus hydrogenii  
PSI – Photosystem I  
qPCR – Quantitative polymerase chain reaction  
QTN – Quantitative trait nucleotide  
RGR – Relative growth rate  
RNA – Ribonucleic acid  
ROS – Reactive oxygen species  
SA – Salicylic acid  
SE – South-East  
SNP – Single nucleotide polymorphism  
SO – Süd-Ost  
SOD – SUPEROXIDE DISMUTASE  
SOC1 – SUPPRESSOR OF OVEREXPRESSION OF CONSTANS 1  
SpDLH – DIENELACTONE HYDROLASE  
SpETHE1 – MITOCHONDRIAL SULFUR DIOXYGENASE 1  
SpGBPL2 – GUANYLATE-BINDING PROTEIN 2  
SpHPL – HYDROPEROXIDE LYASE  
SpLHCB5 – LIGHT-HARVESTING-CHLOROPHYLL-A/B-BINDING PROTEIN 5  
SpLOX2.1 – LIPOXYGENASE2.1  
SpMYBC1 – MYELOBLASTOSIS C 1  
SpPUB4 – U-BOX CONTAINING PROTEIN 4  
SpSBE3 – STARCH-BRANCHING-ENZYME 3  
SpSCAMP3 – SECRETORY CARRIER-ASSOCIATED MEMBRANE PROTEIN 3  
SpUBP7 – UBIQUITIN-CARBOXYTERMINAL HYDROLASE 7

SpYPEL – YIPPEE-LIKE PROTEIN

SRF – SERUM RESPONSE FACTOR

TOC1 – TIME OF CAP EXPRESSION 1

TSR – Target-site resistance

UV – Ultraviolet

$\pi$  – Pairwise nucleotide diversity

2,4-D – 2,4-Dichlorophenoxyacetic acid

# 1. Introduction

Studying the genetic background of life history traits is challenging since the pathways controlling morphogenesis and reproduction in organisms are often very complex. Also, many pathways display strong interaction patterns, meaning that manipulation of one component leads to physiological changes in many other organismal traits (Mauro and Ghalambor 2020). Hormonal pathways are famous examples of the strong interconnectivity of developmental traits. For instance, injection of the alpha-melanocyte-stimulating hormone in the blue morphs of the cichlid species *Astatotilapia burtoni* simultaneously increases pigmentation and aggressiveness, showing that behavior and habitus can be jointly regulated through changes of a single component (Dijkstra et al. 2017). On a genetic level, the joint connection of two or more traits is called pleiotropy (Mauro and Ghalambor 2020). Pleiotropy mostly occurs through one gene controlling several traits. A famous example of pleiotropy is *DAYS TO HEADING* on chromosome 8 (*DTH8*) in *Arabidopsis thaliana*, which decreases flowering rate and increases plant height through regulation of photoperiod sensitivity (Wang et al. 2019b). Alternatively, pleiotropy can also occur through strong linkage between genes. As an example of this, the comb color of a chicken was strongly correlated with egg production - likely through a strong linkage between two genes controlling for ovulation and pigmentation independently (Dong et al. 2019).

Pleiotropy can be of great biotechnological interest, since negative correlations between traits caused by antagonistic pleiotropy, are a major reason why certain traits cannot be optimized simultaneously (Mauro and Ghalambor 2020). Such negative correlations between several traits are also referred to as trade-offs. On the phenotype level, trade-offs determine resource allocation between reproduction and survival (Stearns 1989), or between growth and specialized metabolites (Huot et al. 2014).

A detailed understanding of the genetic basis underlying trade-offs is therefore crucial for improving nutritional value and crop yield in plants. Due to their adaptation to various environments plants show overall great amounts of metabolic variation (Kartseva et al. 2024; Schulz et al. 2015; Chen et al. 2016). Since studying trade-offs mainly relies on correlations of phenotypic parameters (Stearns 1989), high amounts of phenotypic variation are favorable for elucidating their genetic background. Because plants play an important role in global food production, research on plant metabolic variation has been shown to be a valuable resource for understanding pleiotropic gene functions and trade-offs (Cu et al. 2021; Angelovici et al. 2013; Alvarez et al. 2010; Živanović et al. 2020; Fang and Luo 2019).

However, in many cases, such metabolic variations are continuous traits and are therefore reflected by complex genetic architectures (Cu et al. 2021; Zhang et al. 2019). Consequently, the exact contribution of certain gene candidates to a trait is often difficult to determine in many cases, compromising marker-based breeding strategies and the genetic engineering of crops (Fang and Luo 2019). Since environmental factors influence the expression of trade-offs (Stearns 1989), another important question is how different environments have specifically selected for pleiotropic gene functions during evolution.

Based on these challenges this thesis will focus on the elucidation of the genetic basis of metabolic pleiotropy using the duckweed *Spirodela polyrhiza* (Lemnaceae) as model organism. In the first section of the introduction (1.1), I will focus which on how phenotypic traits are affected by variations in plant metabolism. Next, it will be shown which evolutionary principles shaped plant metabolism (1.2). The subsequent section (1.3) will then focus on genome-wide association studies (GWAS) as a tool to determine genetic markers associated with quantitative traits. In the last section (1.4), *S. polyrhiza* will be introduced as a model organism for studying pleiotropic gene function in plants.

## **1.1 Mechanisms of Metabolic Adaptions in Plants**

As sessile organisms, plants must deal with a broad array of environmental changes. As a result of this, plant metabolic traits strongly vary in adaptation to environmental gradients. For instance, parameters like leaf thickness or contents of chlorophyll and carotin increase with elevation, whereas photosynthesis rate, stomatal density and leaf size were shown to decrease (Halbritter et al. 2018). In the case of the duckweed *Lemna minor*, the contents of phenolic compounds and C:N ratios increased with latitude and mean average temperature (Chou et al. 2019). Other metabolic changes are lifestyle dependent. For instance free floating plants were shown to have higher nitrogen and free amino acid contents than submerged plants (Chou et al. 2019). As a consequence of alterations of amino acid composition through age caused by increased rates of proteolysis, many metabolic traits change during plant development (Tilsner et al. 2005). The adaptation to this vast array of stress factors is facilitated through a broad multifunctionality of plant metabolites. Therefore, the first section will focus on how the functional diversity of free amino acids and derived compounds facilitates plant adaptation to different stress factors (1.1.1). The next section will then focus on genetic factors controlling metabolic pleiotropy using herbicide resistance as an example (1.1.2).

### **1.1.1 Adaptive Functions of Free Metabolites to Natural Stresses**

On the molecular level many adaptation processes to environmental conditions are facilitated through changes in free metabolite contents (Hui et al. 2023). The adaptive function of free metabolite levels is reflected by their high genotype-specific differences (Chen et al. 2014; Chen et al. 2016; Fang and Luo 2019). As a consequence of their high importance in stress responses, variations of specialized metabolites were shown to be higher than those for primary metabolites (Chen et al. 2016). In plants, amino acids and derived compounds constitute a major class of free metabolites controlling metabolic functions (Schulz et al. 2015; Schäfer et al. 2016; Hildebrandt et al. 2015; Yang et al. 2020). Since 62% of total ammonium and 32% of total fixed carbon are used for amino acid biosynthesis (Smith et al. 1961), amino acids are major sinks of carbon and nitrogen in plants, explaining their central role in growth dynamics. As such free amino acids fulfill a broad range of systemic functions such as pH regulation, growth regulation, energy supply and defense against biotic and abiotic stressors (Hildebrandt et al. 2015).

Due to their central function in energy metabolism free amino acids are often released during plant developmental processes such as leaf development and seed germination (Tilsner et al. 2005). Since the contents of free amino acids can reach high levels, they substantially contribute to the regulation of turgor within the plant cell (Fukutoku and Yamada 1981; Živanović et al. 2020). This function is especially relevant in conditions when plants suffer strong osmotic stress. During drought, plants were shown to increase intra-cellular contents of L-proline to compensate for water deficit (Živanović et al. 2020). The involvement of amino acids in herbivore defense is mainly explained by their function as precursors for specialized metabolites. Most importantly, L-phenylalanine serves as a precursor for phenolic acids, flavonoids, and stress hormones like salicylic acid (SA).

Among these derived metabolites, flavonoids were shown to have high functional diversity. Through their hydroxy groups they function as chelators of toxic heavy metal ions (Brown et al. 1998) and antioxidants (Muhlemann et al. 2018; Kumar and Pandey 2013). Through their conjugated  $\pi$ -electron system flavonoids are further capable of absorbing UV-light, protecting the plant from photodamage (Tattini et al. 2004). Additionally, certain flavonoids like anthocyanins show a cold-induced biosynthesis and were shown to promote freezing tolerance in plants (Schulz et al. 2015). By controlling ROS-levels, flavonoids interfere with various developmental processes such as pollen tube growth (Muhlemann et al. 2018; Ringli et al. 2008).

### **1.1.2 Genetic Mechanisms of Non-Targeted-Site Resistance**

As a consequence of the functional diversity of free metabolites, several metabolic traits can be influenced by the simultaneous manipulation of a single gene. Among plants, resistance to herbicides constitutes a famous example of this metabolic pleiotropy. Mutations in resistance-conferring genes can be caused by amplification of target gene copies in the genome (Gaines et al. 2010), promotor rearrangements that increase gene expression (Mernke et al. 2011), epigenetic mechanisms (Pan et al. 2019), non-synonymous point mutations or deletions within coding sequences of genes (Yu et al. 2015; Perotti et al. 2019; Maeda et al. 2019). Depending on the complexity of the underlying mechanism, resistance cases can be grouped into two different categories:

1. Target site resistance describes mutations within the molecular target of the herbicide. Per definition, these mutations can either lead to an overexpression of the molecular target (Yannicari et al. 2017) or to a structural change in the protein encoded by the target gene through non-synonymous mutation in the coding sequence (Yu et al. 2015). Since target site resistance only influences the function of a single gene, it is defined as a monogenic trait, conferring a discrete phenotype (Jugulam and Shyam 2019).

2. The counterpart of target-site resistance, non-targeted site resistance (NTSR), describes systemic changes in plant metabolism leading to increased herbicide resistance (Jugulam and Shyam 2019). The non-target-site mechanism can therefore be understood as a metabolic compensation of herbicide-mediated stress through mechanisms like reduced uptake or translocation of herbicide (Dinelli et al. 2006), herbicide efflux (Pan et al. 2021; Prosecka et al. 2009), sequestration (Visnovitz et al. 2008; Ge et al. 2010; Jóri et al. 2007), chemical inactivation of herbicide (Pan et al. 2019; Chun et al. 2002), quenching of reactive oxygen species produced by herbicide (Shaaltiel and Gressel 1986; Lewinsohn and Gressel 1984; Jansen et al. 1989) or changes in signaling/apoptosis (Moretti et al. 2018). Since it requires complex interplay of various pathways that act synergistically together to compensate herbicide-mediated stress, NTSR is often polygenic (Jugulam and Shyam 2019; Keith et al. 2017).

Looking at the gene functions underlying NTSR, we see that a high number of NTSR-associated genes are pleiotropic. A prominent example of this is the CYP450 (cytochrome P450) gene family, which is represented by around 16000 genes within the plant kingdom (Nelson 2018). CYP450 genes encode monooxygenases, catalyzing oxidation reactions and are key players in

the metabolism of defense metabolites like terpenes (Geisler et al. 2013), phytohormones like jasmonic acid (Koo et al. 2011) and flavonoids (Ahmad et al. 2019; Steele et al. 1999). As a consequence of their central function in specialized metabolism many CYP450 enzymes are stress-induced (Steele et al. 1999; Pandian et al. 2020). Pleiotropic effects conferred by CYP450 genes are mainly related to the lack of strong substrate specificity for some of these enzymes. Besides their natural substrates, CYP71A10 metabolizes phenylurea herbicides (Siminszky et al. 2003), whereas CYP71A11 catalyzes the breakdown of chlorotoluron herbicides (Gion et al. 2014). Similar to CYP450 genes, ABC (ATP-binding cassette) transporters, many of which confer resistance to herbicides, show great functional diversity. Through catalyzing transport of alkaloids (Shitan et al. 2003) or the excretion of heavy metals and secondary metabolites (Kim et al. 2007; Khare et al. 2017), ABC transporters show strong functional involvement in drought stress (Kim et al. 2010), heavy metal stress (Kim et al. 2007) or pathogen defense (Khare et al. 2017). Due to their transport function, ABC transporters can allocate resources to herbicide-damaged tissues or catalyze herbicide efflux of herbicides like glyphosate (Tani et al. 2015; Tani et al. 2016; Pan et al. 2021). Since ABC transporters and CYP450 enzymes are crucial for secondary metabolism, resistance mechanisms associated with these genes are likely explained by a structural similarity of their natural target molecules with the herbicide (Chun et al. 2002; Pan et al. 2019; Gion et al. 2014).

Besides chemical similarities between herbicides and secondary metabolites, mechanistic similarities between herbicide-generated stress and environmental stress can explain the pleiotropic effects of NTSR conferring genes. A common stress mechanism of drought, salt and heavy metal exposure is the induction of reactive oxygen species (ROS) in plants (Xiong et al. 2002; Schützendübel and Polle 2002). Since many herbicides act via the production of ROS, plant cell death caused by herbicide exposure is likely occurring via ROS-induced apoptosis similar to many other environmental stress factors (Chen and Dickman 2004; Foyer and Noctor 2005). Genotype-specific differences in apoptosis signaling or quenching of ROS were therefore central for explaining differences in herbicide resistance levels in plants (Van Horn et al. 2018; Melicher et al. 2022; Shaaltiel and Gressel 1986).

Since herbicide resistance is mechanistically associated with stress responses in many cases, high fitness costs can be linked with resistance, because resistance-conferring mutations often compromise the catalytic efficiency of the corresponding gene product (Yu et al. 2015). However, for two reasons, many NTSR mechanisms were not associated with resistance costs (Comont et al. 2019). First, in NTSR compensatory mutations, which recover fitness costs and

resistance-conferring mutations are thought to evolve simultaneously (Comont et al. 2019). Second, in contrast to TSR mechanisms, which are mostly constitutive traits (Yu et al. 2015; Yanniccari et al. 2017), some NTSR mechanisms are thought to be inducible traits (Keith et al. 2017; Lewinsohn and Gressel 1984; Moretti et al. 2018), which is a more resource-efficient way to cope with metabolic costs as we will see in section 1.2.

## **1.2 Evolutionary Origin of Plant metabolic Diversity**

Depending on the strength and duration of environmental stimuli plants may express defense constitutively or make it inducible. Inducible defenses provide more general but unspecific protection against stressors compared to constitutive defenses (Murren et al. 2015).

Phenotypic costs for the expression of traits were shown to be strongly environmentally dependent (Murren et al. 2015), whereas the evolution of plastic responses such as inducible defenses requires heterogenous environmental setups. In agreement with this concept, exposure to complex stresses, like simultaneous applications of several herbicides to plants were shown to favor generalist NTSR evolution, whereas applications of a single herbicide favored the evolution of TSR mechanisms (Comont et al. 2020). Since NTSR to herbicides is generally defined by a fast or constitutive upregulation of the plants general, unspecific stress response it has likely evolved from defense strategies against complex stress factors (Keith et al. 2017; Dyer 2018).

Because, as a consequence of their immobility, plants have to cope with fast environmental fluctuations, making traits plastic might be seen as a common strategy to save costs in the absence of natural stressors (Campbell and Kessler 2013). Consequently, a remarkably large portion of plant life-history traits are very plastic compared to other organisms (Sun et al. 2023; Campbell and Kessler 2013). Approximately 54% of variations in plant size are thought to be explained through phenotypic plasticity (Chevin and Lande 2011).

Since fitness costs can be associated with pleiotropic gene functions, the expression of many defense-related genes is inducible or tissue-specific (Upadhyay et al. 2020; Wada et al. 2014; Wang et al. 2020). This results in characteristic temporal and spatial expression patterns of defense traits (Brütting et al. 2017). The following section (1.2.1) deals with strategies of plants to maintain spatial resource allocation patterns of metabolites. Next, I will introduce how environmental factors influence the evolution of inducible plant-life history traits, using the mating system as an example (1.2.2).

### **1.2.1 Resource Allocation Theories in Plant Defense**

On a systemic level, plants keep the balance between growth and defense through different production rates of defensive metabolites and their allocation to tissues as part of their stress response, known as growth-defense trade-off (1.2.1.1). Consequently, resistance to stress factors was often associated with reduced allocation of resources for reproduction (Comont et al. 2019). Also, plants save resistance-associated costs by efficient allocation of defense resources to metabolically more valuable tissues, which is known as optimal defense theory.

#### **1.2.1.1 Growth-Defense Trade-offs**

Fitness costs originating from stress responses can occur through different ways. Since plant growth can be interpreted as the conversion of primary metabolites into cells (Hilty et al. 2021; Züst and Agrawal 2017), any diversion of primary metabolites for secondary metabolism would compromise plant growth. According to the resource-drain hypothesis, carbon for growth and primary metabolite biosynthesis becomes less available, when plants produce specialized metabolites (Foyer et al. 2007). Besides this, the biosynthesis of specialized metabolites often requires many elements like sulfur and nitrogen, which are limiting factors for plant growth (Foyer et al. 2007). In agreement with this concept increased production of anthocyanins was associated with reduced growth in *S. polyrhiza* genotypes (Oláh et al. 2009). Also, many specialized metabolites are auto-toxic to the plant and require energy-intensive sequestration (Halkier and Gershenzon 2006) or detoxification mechanisms (Dick et al. 2012; Li et al. 2021) to prevent cell damage.

#### **1.2.1.2 Optimal Defense Theory**

Since stressors like herbivores often attack only certain parts of the plant specifically, defense reactions must be coordinated in a tissue or organ-specific manner. The central idea of this so-called optimal defense theory is that defense metabolites are transported to tissues with high metabolic importance for the plant, like flowering tissue (Brütting et al. 2017). The resulting tissue-specific differences in specialized metabolite contents ensure increased protection against stress factors. Since glucosinolates are produced in older leaves and are transported to younger leaves, herbivores were showing stronger avoidance of younger leaves than for older leaves (Hunziker et al. 2021). On a regulatory level the allocation of defense resources to tissues with increased metabolic importance is mediated through cytokinins (Brütting et al. 2017). These differences in specialized metabolite contents between tissues were caused by different

genetic control mechanisms, resulting in tissue-specific expression patterns of many genes (Chen et al. 2016).

### **1.2.2 Environment-Driven Evolution of Mating System**

Besides plastic responses, trade-offs and resource allocation patterns are also of central importance for plant morphogenesis and evolution. An example of this is the evolution of plant mating systems. Since the formation of reproductive organs and seed production are costly, an increased resource allocation to defense is thought to compromise the development of the sexual reproductive system in a similar way like growth (Ramos and Schiestl 2019, 2020). Genetically reproductive traits and defense traits can be associated via pleiotropy, since mutations changing reproduction might also change resource allocation between growth and defense (Johnson et al. 2015). This pleiotropy can be conferred by one gene functioning in several biosynthetic pathways or transport processes of metabolites controlling flower development and defense simultaneously. For instance, through their function as floral color pigments, anthocyanins promote the attraction of pollinators and herbivores to plants (Johnson et al. 2015) and simultaneously mediate plant resistance against cold stress (Schulz et al. 2015). Increased allocation of anthocyanins to flower tissues might, therefore, compromise plant resistance to environmental stress factors.

In the case of *Brassica rapa* increased resource allocation to defense as a consequence of herbivory led to the evolution of fewer flowers that were less attractive to pollinators (Ramos and Schiestl 2019). As a consequence of the resulting pollen limitation, plants evolved higher rates of selfing for reproductive assurance through reduced herkogamy (Ramos and Schiestl 2019). Since selfing leads to inbreeding depression through decreasing gene flow and effective population size (Eckert et al. 2010; Kuester et al. 2017), herbivory can trigger coevolution of mating system and herbivore resistance at the costs of reduced plant fitness through inbreeding. Reduction of gene flow and inbreeding can also promote the spread of herbicide resistance conferring mutations in plant populations. For *Ipomoea purpurea* self-pollination rates through reduced herkogamy were higher in genotypes with high herbicide-resistant levels compared to the ones with lower resistance (Kuester et al. 2017). Through the reproductive isolation of resistant genotypes, alleles driving selfing associate with loci enhancing herbicide resistance, which in turn drives faster elimination of susceptible alleles since allelic segregation in selfing populations increases homozygosity levels (Kuester et al. 2017). On an environmental scale, selfing was therefore more frequent in fragmented or disturbed environments where outcrossing

is limited by the availability of pollen (Eckert et al. 2010). Conversely, increased outcrossing occurred preferentially in environments with relaxed growth-defense trade-offs, allowing more resource allocation to pollinator attraction (Eckert et al. 2010).

Besides this, many plant species can also reproduce clonally to avoid costs associated with sexual reproduction (Wang et al. 2024). The avoidance of such costs is especially helpful during the colonization of new environments since it allows faster reproduction, but might decrease fertility due to the accumulation of deleterious mutations as long-term consequences (Barrett 2015). Clonal reproduction is often connected to aquatic environments where genotypes show long-distance dispersion, because the production of vegetative shoots minimizes the risk of death and leads to an increased division of labor (Barrett 2015). Also, carbon resources are more limited in aquatic environments disfavoring the production of costly reproductive organs (Santamaría 2002).

### **1.3 Genome-Wide Association Studies for Studying Metabolism**

As shown in the previous section plant metabolism is characterized by strong trait correlation patterns. Since strong trait correlation easily leads to false positive signals, genetic association studies aiming to elucidate the genetic basis of plant metabolism often require large sample sizes to have sufficient power to detect true causative loci (Angelovici et al. 2017; Chen et al. 2014; Chen et al. 2016). Due to this high degree of complexity and since many inducible metabolic traits are heritable (Campbell and Kessler 2013), GWAS can be used as a tool to study the genetic background of plant metabolism. A GWAS conducted on shade avoidance in *A. thaliana* lead to the identification of markers associated with the phytochrome C gene and phytohormone signaling and biosynthesis (Filiault and Maloof 2012), providing valuable insights into the genetic basis of a plastic trait.

The concept of genetic association studies first emerged around 2000 and has received lots of methodological improvements since then. The first association studies were conducted with small sets of genetic markers on regions of interest identified in other studies (Tibbs Cortes et al. 2021; Thornsberry et al. 2001). After the availability of SNP datasets representative for entire genomes, created in the human genome project, GWAS was finally possible for *Homo sapiens*. Since association tests in large sets of genetic markers from individuals with different degrees of relatedness would require methods to control population stratification, mathematical methods for estimating population structure were already developed before the first genome-wide SNP datasets were available for *Homo sapiens* (Tibbs Cortes et al. 2021). The aim of

population structure estimates is to correct for loci correlated by relatedness of individuals to prevent an inflation of  $P$ -values caused by relatedness (Pritchard et al. 2000a). As an example, the STRUCTURE software works through the definition of subpopulations in the dataset based on null markers (Pritchard et al. 2000a).

The generalized linear model (GLM) was then among the first approaches which allowed correcting for population structure by adding subpopulations defined by STRUCTURE as cofactors into the model (Pritchard et al. 2000b). After the identification of population structure, tests for significant association were conducted within each subpopulations structure (Pritchard et al. 2000b) (Figure 1). After publication of the draft human genome the first GWAS was successfully conducted on the myocardial infarct risk of *Homo sapiens* (Ozaki et al. 2002). However, the first GWAS conducted in plants on the traits flowering time and pathogen resistance in *A. thaliana* in 2005 identified many false positives signals (Aranzana et al. 2005). Since STRUCTURE population analysis assumes random mating and strong population admixture with individuals jointly belonging to two or more subpopulations (Pritchard et al. 2000a), it is not suitable for GWAS in selfing species, which have a long history of isolation by distance and inbreeding, explaining the high amounts of false positives (Aranzana et al. 2005).

The Mixed Linear Model (MLM), developed in 2006, splits individuals relatedness into two components: kinship, which estimates relatedness between individuals as identity by descent and population structure, therefore assuming no homogenous subpopulations (Yu et al. 2006). Due to this improvement, MLM performed better in GWAS conducted for *A. thaliana* than GLM (Yu et al. 2006).

A further improvement of computational power on GWAS was achieved through the development of multi-locus models, which allowed the identification of small effect loci (Tibbs Cortes et al. 2021). Running through several iterations, the most significant SNP is added as covariate in each iteration (Tibbs Cortes et al. 2021; Segura et al. 2012). The model is then iterated till covariance explained by the remaining markers is 0 or till a user-defined threshold (Tibbs Cortes et al. 2021; Segura et al. 2012). The first multi-locus model MLMM (multi-locus mixed model), developed in 2012, performed stepwise MLM, incorporating significant markers simultaneously as covariates, but still being computationally expensive (Segura et al. 2012).

The problem of lacking computational efficiency was solved by the development of the Fixed and random model Circulating Probability Unification (FarmCPU) (Liu et al. 2016). Being also a multi-locus model, FarmCPU divided the genome into bins of equal sizes and selected the

marker with the lowest  $P$ -value from each bin as quantitative trait nucleotide (QTN). The best combination of bin and QTNs is then determined via a random effect model (Liu et al. 2016).

The major problem with FarmCPU is that it assumes significant markers to be homogeneously distributed across the genome and its random model, which is used for kinship calculation is computationally very expensive (Liu et al. 2016; Huang et al. 2019). Like FarmCPU, the Bayesian-information and linkage-disequilibrium iteratively nested keyway method (BLINK) also uses maximum likelihood for calculating iteration thresholds (Huang et al. 2019). However, by replacing the bin method with Bayesian criteria on linkage disequilibrium information, BLINK eliminates the computationally expensive random effect model, allowing significant markers to be non-homogeneously distributed across the genome (Huang et al. 2019) (Figure 1).

Since GWAS usually tests for associations among huge amounts of markers, significance thresholds have to be adjusted to counter the multiple testing problem. To correct for this, previous GWAS used Bonferroni corrections or minor allele frequencies to correct significance thresholds according to the number of markers studied (Tibbs Cortes et al. 2021). More recently, permutation-based thresholds have become increasingly popular in GWAS (Che et al. 2014; John et al. 2022). Permutation-based approaches calculate significance thresholds through multiple randomizations of phenotypic values. The significance score for permutation-based GWAS is then calculated as the fraction of all permutations, which gives more significant results than the original dataset (Backes et al. 2014). Permutation, therefore, allows a non-parametric estimate of significance thresholds in situations when the sample size is low, or the distribution of phenotypic values is unclear for another reason (Che et al. 2014).

Together, the recent methodological improvements in increasing power and computational efficiency render GWAS as an exceptionally suitable method for studying the genetic basis of metabolic traits in plants.

**Figure 1: Timeline depicting selected key events in the development of genome-wide association studies (GWAS).**

## 1.4 Metabolism of *Spirodela polyrhiza*

Studying the genetic mechanism of metabolic traits in plants using genetic association studies requires the selection of a suitable model organism. Due to their strongly reduced body plans but high metabolic and genetic diversity reflected by their worldwide distribution (Acosta et al. 2021; Tippery and Les 2020), duckweeds are good candidates for studying the genetics underlying plant metabolism. In this chapter, I aim to introduce the physiological features of the duckweed *Spirodela polyrhiza*, qualifying it as a model for studying metabolic pleiotropy in plants.

Duckweeds are small, free-floating, aquatic macrophytes inhabiting freshwater systems. Phylogenetically duckweeds are monocots and were previously classified as a subfamily of Araceae (Lemnoidea) (Nauheimer et al. 2012). However, the branching from the remaining Araceae happened 103.6 million years ago (Nauheimer et al. 2012) and duckweeds form a physiologically and morphologically well-defined class within monocots (Sree et al. 2016). Because of that, they were grouped as an own family named Lemnaceae, which contains 36 species and five genera: *Spirodela*, *Landoltia*, *Lemna*, *Wolffiella* and *Wolffia*, more recently (Sree et al. 2016; Bog et al. 2020). The evolutionary trajectory of Lemnaceae led to a simplification of their body plan, with the two most ancestral genera *Spirodela* and *Landoltia* (Tippery et al. 2015) showing the greatest morphological differentiation.

Since *S. polyrhiza* has the smallest genome and the most complex body plan among duckweeds (Wang et al. 2014; Xu et al. 2019), it became an interesting model system for studying the genetic basis of duckweed metabolism (Wang et al. 2014). In the case of *S. polyrhiza*, its body consists of a roundish leaf/stem-like structure, which is referred to as a frond and several adventitious roots (Acosta et al. 2021; Landolt 1988). The high amounts of aerenchyma in frond tissue create enough buoyancy to let them float on the water surface (Ziegler et al. 2023). Each frond has two meristematic pockets from which new daughter fronds emerge via asexual budding. Clusters of several fronds are called colonies and are connected via stipes (Landolt 1988). Further, *S. polyrhiza* shows a very reduced shoot structure at the base of its stipe (Acosta et al. 2021; Landolt 1988). Like other duckweeds, *S. polyrhiza* is capable of flowering but almost entirely reproduces asexually, remaining in the juvenile stage for its entire life, which is why duckweeds were seen as neotenus plants (Wang et al. 2014; Hoang et al. 2019). *S. polyrhiza* is world-widely distributed and present in all climate zones except of deserts (Ziegler

et al. 2023). The adaptation to these different environmental setups required large metabolic adaptations for this species.

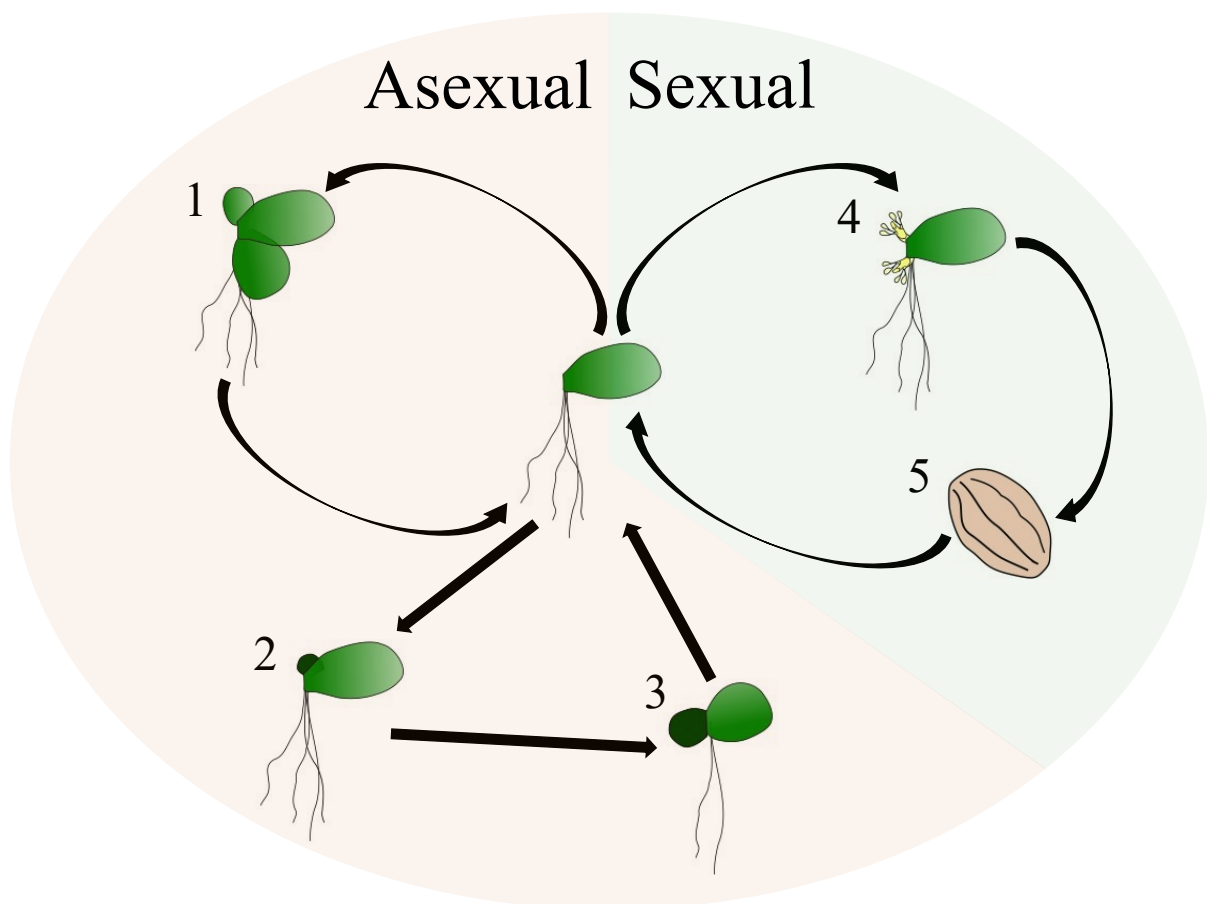

Caused by differences in climatic factors, aquatic environments strongly differ in nutrient levels (McDowell et al. 2020), requiring high metabolic flexibility of *S. polyrhiza*. As an adaptation to different nutrient levels in water *S. polyrhiza* can switch between heterotrophy, mixotrophy and autotrophy (Sun et al. 2023). For instance, the presence of an organic carbon source favors the mixotrophic growth of duckweed (Firmin et al. 2022), which is characterized by reduced photosynthesis rate, protein content and higher contents of rubisco compared to phototropic growth (Sun et al. 2023). Under phototropic conditions, *S. polyrhiza* shows elevated contents of secondary metabolites such as flavonoids (Sun et al. 2023). Together, these findings reveal high levels of adaptation to environmental conditions involving large metabolic reprogramming. In the following sections, we discuss how metabolic and genetic features shape growth (1.4.1), development (1.4.2) and stress response (1.4.3) in *S. polyrhiza*, before finally looking into the genetic diversity underlying these traits (1.4.4).

#### **1.4.1 Growth and Reproduction**

In its asexual reproduction mode *S. polyrhiza* reproduces through alternating detachment of daughter fronds from its vegetative pouches. The second daughter frond detaches from the other pocket as the first daughter with some delay (Landolt 1988) (Figure 2). Since asexual reproduction does not require costly investments in reproductive organs and seed development, reproduction can go at much shorter time scales, as shown in section 1.2.2, making *S. polyrhiza* one of the world's fastest-growing angiosperms with a biomass duplication time of less than two days (Ziegler et al. 2015). For overwintering, *S. polyrhiza* produces turions, which sink to the ground and germinate in spring. The rate of sexual reproduction is likely less than 1% for this species (Ho et al. 2019). However, this value might also reflect genetic variation due to past sexual reproduction events (Ho et al. 2019).

The high amount of clonal reproduction is thought to have been beneficial during recent migration events allowing fast colonization of new aquatic habitats (Wang et al. 2024; Xu et al. 2019). Since nutrient levels, light and temperature are relatively constant over a day within aquatic environments, loss of genes associated with environmental synchronization of growth might have favored the evolution of an asexual reproduction style, as discussed in section 1.2.2 (Michael et al. 2021). Supporting this argument *S. polyrhiza* has 1/3 less genes involved in light signaling and circadian clock regulation compared to *Oryza sativa* (Michael et al. 2021).

These asexual growth rates further show large intraspecific variation in duckweed (Sree et al. 2015; Ziegler et al. 2015). Physiologically, these growth rates were positively correlated with increased metabolic activities such as the photosynthesis rate (Sree et al. 2015). Furthermore, intraspecific differences in growth rates of *S. polyrhiza* were shown to be caused by differences in resource allocation (Sun et al. 2023). In this regard, lower starch content was connected to increased growth rates (Sun et al. 2023). Since plants with larger frond sizes were shown to have lower frond duplication rates than plants with smaller frond sizes, a second trade-off exists between the duplication of fronds and the increase of frond area (Strzałek and Kufel 2021). Because frond enlargement is connected to shady environments, growth investment to larger frond size might represent a shade adaption strategy (Strzałek and Kufel 2021).

**Figure 2: Sexual and asexual reproductive modes of *Spirodela polyrhiza*.** Verified connections between life stages are shown with black arrows: The by far largest amount of reproduction occurs via asexual budding of daughter fronds from the mother frond (1). For overwintering, *S. polyrhiza* produces dark green turions (2), which sink to the ground and germinate in spring, giving rise to new daughter fronds (3). Under stressful environmental conditions, flowers can be formed from the meristematic pockets (4). Seed formation (5) and

germination processes were only described as extremely rare natural observations (Saeger 1929; Landolt 1986).

#### **1.4.2 Regulation of Organ Development and Morphogenesis**

The simplification of the body plan and decrease in developmental complexity is reflected by reduced contents of protein-coding genes in the *S. polyrhiza* genome. With a total of number of 19623 genes, *S. polyrhiza* has 28% and 50% fewer protein-coding genes compared to *Arabidopsis thaliana* and *O. sativa*, respectively (Wang et al. 2014). Among these gene losses were mainly genes involved in lignin biosynthesis and cell wall organization, which have critical functions for the formation of complex tissues in higher plants (Wang et al. 2014), explaining the overall morphological simplification of *S. polyrhiza*.

Genetically the suppression of flowering might be explained through an increased copy number of genes and microRNAs repressing the transition from juvenile to adult stage increase (Wang et al. 2014). In addition to that, duckweeds seem to be characterized by an exceptionally high loss of genes involved in flower formation. The genome of *S. polyrhiza* lost five out of 16 clades of MIKCC<sup>c</sup>-group MADS-box genes (Gramzow and Theißen 2020), making it the genome with the highest simultaneous loss of MADS-box genes among 26 tested plant species (Gramzow and Theißen 2015).

Consequently, the floral organs of *S. polyrhiza* are of very rudimentary shape (Figure 3) and are only rarely observed in nature. In contrast to most plants, where flowering rates are mostly linked to seasonal changes in day length and irradiance rather than stress, flowering in duckweeds can be induced by environmental stress such as lack of nutrients (Shimakawa et al. 2012; Takeno 2016). Possibly this decoupling of flowering from daylength is explained by the loss of many genes associated with light signaling (Michael et al. 2021), as mentioned in the previous section (1.4.1).

Indeed, *S. polyrhiza* flowers could only be induced through the treatment of high-density cultures with SA (Fourounjian et al. 2021; Khurana and Maheshwari 1980). Since SA functions as a stress hormone in plants (Huot et al. 2014), flowering might be naturally induced under stressful conditions to promote species survival under conditions unlikely for the individual to survive (Shimakawa et al. 2012; Wada et al. 2014). On a molecular level this happens through a synchronization of SA biosynthesis with that of flavonoids (Shimakawa et al. 2012), which constitute a major class of defense metabolites in *S. polyrhiza* (Böttner et al. 2021; Oláh et al. 2009). Through catalyzing the first step in both SA and flavonoid biosynthesis out of L-

phenylalanine the phenylalanine ammonia lyase (PAL) plays a central role in this synchronization process (Gordon and Koukkari 1978). PAL is stress-inducible, showing increased expression under poor nutritional status (Shimakawa et al. 2012) and low temperature (Wada et al. 2014), explaining the joint induction of flowering and flavonoid biosynthesis by stress in duckweed under these conditions (Takeno 2016).

However, older studies described seed production in *S. polyrhiza* after pollination as an extremely rare biological event (Landolt 1986; Saeger 1929). A more recent attempt to experimentally produce seed in *S. polyrhiza* has not been successful (Fourounjian et al. 2021). Eventually, these conflicting results indicate, that some genotypes of *S. polyrhiza* have lost the ability to complete their sexual reproduction cycle entirely. Low rates of seed production might also refer to self-sterility in *S. polyrhiza*, as shown for *L. minor* (Landolt 1986). A possible explanation for the rarity of seed development is that many genes whose orthologs were involved in seed formation were upregulated during the transition from the vegetative frond stage to the resting turion stage (Pasaribu et al. 2023). This suggests a re-functionalization of genes controlling seed development for turion production in *S. polyrhiza* (Pasaribu et al. 2023).

**Figure 3: Flower morphology in *Spirodela polyrhiza*.** A: Two flowers emerge from the meristematic pockets of a mother frond after six weeks induction with 1  $\mu$ M Salicylic acid and 25  $\mu$ M EDDHA in Hoagland medium. The red circle highlights a single flower, illustrated in greater detail (B) B: *S. polyrhiza* flowers consist of four stamens, which are further divided into anthers (A.) and filaments (F.) and one pistil with pigmented stigma (S.) and short style (St.). The floral organs are attached to a receptacle (R.). Pictures: © Martin Höfer

### 1.4.3 Stress-Response to Environmental Factors

Gene loss and re-functionalization events also seem to be characteristic of stress responses in this duckweed species. As a consequence of its aquatic lifestyle, *S. polyrhiza* is confronted with large amounts of bacterial and viral pathogens, which is reflected by an increase of gene families involved in antimicrobial defense and immune response on the genome level (Wang et al. 2014). Intriguingly, Lemnaceae were shown to lack the EDS1 (ENHANCED DISEASE SUSCEPTIBILITY 1) pathway, which is a key pathway for microbial defense in higher plants (Baggs et al. 2022). Instead defense reactions towards pathogen infection were mainly characterized through the upregulation of CYP450 genes, which are involved in secondary metabolite biosynthesis and genes encoding antimicrobial peptides (Baggs et al. 2022). Together, this suggests that specialized metabolites play a central role in duckweed defense towards pathogens.

This hypothesis is further supported by the antimicrobial activities of duckweed exudates, which are rich in flavonoids (Ziegler et al. 2023). Also, the overall high concentrations of flavonoids in duckweed extracts might contribute to preventing systemic infections of duckweed tissue (Dan et al. 2022). Flavonoids were further shown to play a central role in stress responses towards environmental factors (Zhao et al. 2015). Different flavonoid classes seem to have stress-specific functions in duckweed. Whereas anthocyanins were shown to protect *S. polyrhiza* specifically against UV light and Cr (VI) mediated stress (Oláh et al. 2009; Böttner et al. 2021), luteolins protect the plant from copper-induced stress (Böttner et al. 2021). At an organismic level, high amounts of reactive oxygen species produced by these heavy metals are compensated through a temporal increase of antioxidant levels such as glutathione (GSH), allowing *S. polyrhiza* to accumulate high amounts of copper and cadmium (Zhao et al. 2017). Lacking the possibility of sexual reproduction almost entirely, duckweeds seem to possess a trans-generational stress memory via methylation signals. For instance, CHG methylation levels showed temperature effects with high transgenerational stability (Van Antro et al. 2023). This suggests that duckweeds can inherit their responses to environmental stress through an epigenetic mechanism, allowing fast adaptations to new conditions for the following generations.

### 1.4.4 Genetic Diversity

As a consequence of this asexual reproduction-mode, favoring non-genetic inheritance, *S. polyrhiza* has an exceptionally low mutation rate (Xu et al. 2019). Its low genetic diversity is also reflected by low methylation levels (Wang et al. 2024) and pairwise nucleotide diversity

( $\pi = 0.00093$ ) (Xu et al. 2019). These features are explained by a high portion of clonality even for genotypes separated through large geographic distances. Even though the mutation rate is quite low, *S. polyrhiza* has a large effective population with a size of  $9.8 \times 10^5$ , possibly due to its high census population size and worldwide distribution (Xu et al. 2019).

A genetic analysis of the *S. polyrhiza* diversity panel revealed the existence of 159 clonal families (Wang et al. 2024). These genotypes could be grouped into four genetic populations named after their preferred geographic distribution: Europe, SE-Asia, India and America (Xu et al. 2019). A reason for this high clonality might be that the *S. polyrhiza* genome seems to have experienced only weak purifying selection, as indicated by the high  $K_a/K_s$  ratio of 0.495 (Ho et al. 2019).

In addition to that *S. polyrhiza* has one of the smallest genomes among duckweeds with only 158 Mbp containing a high density of protein-coding genes (Wang et al. 2014). Since large sample sizes are required to detect common variants with small effects (Duncan et al. 2019), the combination of low mutation rate, large effective population size and compact genome make *S. polyrhiza* an ideal candidate for genetic association studies to explore the genetic foundation explaining heritable metabolic adaptations.

## 2. Aims of this Thesis

Due to its small body size and high reproduction rate, *S. polyrhiza* is highly suitable for large-scale phenotypic screening procedures to identify phenotypic variation. From a genetic perspective the low genetic diversity and low mutation rate of *S. polyrhiza* (Xu et al. 2019) reduce the number of false positives in GWAS.

Also, due to their high susceptibility to bipyridinium herbicides (Tyler et al. 2006; Cedergreen et al. 2007), duckweeds were used as bioindicator species for herbicide pollution in freshwater systems (Funderburk and Lawrence 1963). For duckweeds, resistance to bipyridinium herbicides was described previously (Tyler et al. 2006), suggesting the existence of great variation in resistance levels. Mechanistically, bipyridinium herbicides like diquat act through diversion of electrons from photosystem I (PSI), creating reactive oxygen species through the Mehler-like reaction (Farrington et al. 1973; Hawkes 2014). Bipyridinium herbicides have several binding places on PSI, whereas the Fe-S cluster at center B within PSI are the main site of electron acceptance (Fujii et al. 1990).

Since the binding place of bipyridinium herbicide is unspecific, the evolution of target-site resistance mechanisms through structural modifications of PSI is unlikely. As consequence of

this, resistance to bipyridinium herbicides is mainly conferred via non-targeted-site mechanisms (Visnovitz et al. 2008; Shaaltiel and Gressel 1986; Yu et al. 2010), which is why the genetic architecture underlying these resistance traits is likely very complex. Due to the above-mentioned advantages, we aim to use *S. polyrhiza* as a model system to explore NTSR mechanisms to the bipyridinium herbicide diquat.

Besides its high susceptibility to herbicides, *S. polyrhiza* has considerable nutritional value, reflected by its high contents in flavonoids, protein and starch (Smith et al. 2024). Because of that, *S. polyrhiza* is used for bioethanol production as well as human and animal feedstock (Acosta et al. 2021). Further biotechnological optimization of *S. polyrhiza* requires identification of quantitative trait nucleotides (QTNs) to improve free metabolite contents.

Related to that, this thesis has three central goals:

1. We first aim to elucidate the phenotypic variation in resistance levels to the bipyridinium herbicide diquat and to identify candidate genes associated with this NTSR trait using GWAS.
2. Next, we aim to identify genetic associations explaining variation in free metabolite contents and growth using GWAS.
3. Using population genetics methods, we plan to identify candidate genes under species and population-wide selection, determining metabolic and life-history features in *S. polyrhiza*. Among the candidates identified in the previous GWAS to gain insights into the evolution of metabolic traits in *S. polyrhiza*.

Since the identification of gene candidates controlling metabolism using GWAS involves high-throughput phenotyping, several pre-tests will be conducted to determine the herbicide screening concentration and the endpoint of the toxicity assays. The screening concentration for diquat will be determined using a two-step approach. First, we will narrow down the range of potential concentrations in a dose-response experiment with two genotypes. Furthermore, duration and inoculum size will be adapted with this first test. Next, we estimate the broad-sense heritability of diquat resistance through repeated testing of 20 different genotypes at two different diquat concentrations in two batches. For the herbicide screening, we will select the concentration causing the highest heritable variation within this pre-liminary set of 20 genotypes.

For the screening, genotypes were screened under diquat and control conditions in triplicate (Figure 4). Fitness under diquat was expressed relative to the untreated control. Due to the high number of genotypes tested, the assay must be split up into five batches. To correct for batch

effects, the resistance of each genotype was standardized to that of genotype SP028, which was analyzed throughout all batches as an internal standard.

The sampled plant material will be freeze-dried for biomass measurement and metabolite analysis. The diquat treated samples were used for measurement of the diquat tissue concentration. Control samples were used for measurement of free metabolite contents, quantifying the concentrations of 42 free metabolites, including eleven phytohormones, eleven specialized metabolites and 20 amino acids and derived compounds, using HPLC-MS. Broad sense heritability of growth and free metabolite concentrations were calculated from repeatedly analyzed genotypes. To further characterize the physiological basis of the phenotypic variation of resistance, we determined the eight most resistant and eight most susceptible genotypes from the herbicide screening procedure in a dose-response experiment measuring fitness under diquat exposure. The freeze-dried plant material from these tests will be used for the quantification of diquat uptake kinetics and glutathione and ascorbate contents to evaluate the physiological effects of diquat resistance in genotypes. Since differences in growth speed between genotypes might have affected the diquat resistance in our fitness test, we measured chlorophyll fluorescence as  $F_v/F_m$  and  $F_v'/F_m'$  in a time course experiment under high diquat concentrations to confirm results from screening experiments. We will finally conduct GWAS on growth, free metabolite contents and diquat resistance to discover the genetic basis of metabolic traits using the *vcf2gwas* platform (Vogt et al. 2021). To gain insights into evolution metabolic traits in *S. polyrhiza*, we will identify candidate genes under species-wide or population-wide selection using results from our population genetics study on this plant. The expression of the most important candidate genes identified using GWAS or selection analysis will be checked using qPCR.

**Figure 4: Schematic workflow of phenotypic characterization of 138 *Spirodela polyrhiza* genotypes.** Genotypes were propagated in Erlenmeyer flasks for 14 days, prior to the toxicity assays. For measuring diquat resistance each genotype was cultivated in triplicates under control conditions and at 10 nM diquat for 7 days. For each genotype, diquat toxicity was determined as growth inhibition measured through frond area, frond number, fresh weight and dry weight relative to an untreated control. In separate experiments genotype-specific differences in herbicide uptake, chlorophyll fluorescence kinetics and antioxidant levels were determined under diquat exposure. For each genotype, constitutive levels of free amino acids, specialized metabolites and phytohormones were measured using LC-MS.

### 3. Articles

#### 3.1 Genetic Mechanism of Non-Targeted-Site Resistance to Diquat in *Spirodela polyrhiza*

##### 3.1.1 Summary

In this project, we focused on exploring the physiological and genetic basis of diquat resistance in the giant duckweed *Spirodela polyrhiza*. To examine intraspecific variation in resistance levels, we screened 138 genotypes of *S. polyrhiza* for their fitness under diquat treatment. The screening revealed differences in resistance levels by factor 8.5 between the most resistant genotype SP050 and the most susceptible genotype SP011. To check the involvement of transport-associated processes in diquat resistance, we measured the diquat tissue concentration for each genotype at the end of the screening procedure using LC-MS. Diquat tissue concentration was positively correlated with susceptibility to diquat. Analyzing genotype-specific uptake kinetics, we found that SP050 showed reduced herbicide uptake after 24h of diquat exposure compared to SP011. Genotype-specific antioxidant protection towards diquat-induced oxidative stress was measured through examination of superoxide dismutase (SOD) activity and measurements of glutathione and ascorbate contents in SP050 and SP011. SP050 showed increased antioxidant protection in terms of elevated SOD activity and increased contents of reduced glutathione and ascorbate relative to their oxidized counterparts compared to SP011. Conducting a genome-wide association study (GWAS) on resistance levels of the screened genotypes using SNPs and structure variations as input, we identified three genetic markers located within a *MITOCHONDRIAL SULFUR DIOXYGENASE* (*SpETHE1*), the *LIPOXYGENASE2.1* (*SpLOX2.1*) and *GUANYLATE-BINDING PROTEIN* (*SpGBPL2*) to be associated with resistance. Studying the expression of *SpETHE1* using qPCR we did not find any difference for this gene between SP050 and SP011, making a direct involvement of *SpETHE1* in diquat resistance unlikely. Studying genes in close distance to *SpETHE1*, we found *DIENELACTONE HYDROLASE* (*SpDLH*) and the *STARCH-BRANCHING-ENZYME 3* (*SpSBE3*) showing reduced expression in SP050 compared to SP011. Taken together, this study suggests that uptake and antioxidant processes jointly contributed to diquat resistance in *S. polyrhiza*. Whereas antioxidant mechanisms seemingly provide short-term protection against diquat-induced oxidative stress before transport-associated processes enable a long-term fitness benefit under diquat exposure. Further, the study associated genes involved in stress-response pathways (*SpETHE1*, *SpDLH* and *SpGBPL2*) and starch metabolism (*SpSBE3*) with diquat resistance.

### 3.1.2 Zusammenfassung

Der Fokus dieses Projektes lag in der Charakterisierung von physiologischen und genetischen Mechanismen, die Resistenz gegen das Herbizid Diquat in *Spirodela polyrhiza* vermitteln. Zur Bestimmung der intraspezifischen Varianz an Resistenzen wurden 138 Genotypen von *S. polyrhiza* hinsichtlich der Inhibition von Fitnessparametern charakterisiert. Der resistenteste Genotyp SP050 zeigte eine um den Faktor 8.5 höhere Resistenz als der am wenigsten resistente Genotyp SP011. Um eine Beteiligung von Transport-assoziierten Mechanismen an der ermittelten Resistenz zu testen, wurde die Gewebekonzentration von Diquat für sämtlich Genotypen nach Ende der Diquat Behandlung mittels LC-MS bestimmt. Die Diquatkonzentration des Pflanzengewebes zeigte eine positive Korrelation mit der Inhibition durch das Herbizid. Eine Analyse der Genotyp-spezifischen Aufnahmekinetik des Herbizids ergab, dass SP050 eine niedrigere Akkumulation nach 24-stündiger Exposition zeigte als SP011. Weiterhin wurden Genotyp-spezifische antioxidative Mechanismen durch Messungen der Aktivität der Superoxiddismutase (SOD) und der Konzentrationen von L-Ascorbinsäure und Glutathion untersucht. Verglichen mit SP011 zeigte SP050 erhöhte SOD Aktivität sowie höhere Werte an reduzierten Glutathion und L-Ascorbinsäure relativ zum Gesamtantioxidantienpool nach Exposition durch Diquat. Eine Genomweite Assoziationsstudie (GWAS) für SNPs und strukturelle Variationen, durchgeführt an Diquatresistenzleveln von 138 Genotypen, assoziierte drei Marker innerhalb von Gensequenzen der *MITOCHONDRIAL SULFUR DIOXYGENASE 1* (*SpETHE1*), der *LIPOXYGENASE2.1* (*SpLOX2.1*) und des *GUANYLATE-BINDING PROTEIN 2* (*SpGBPL2*) mit Diquat Resistenz. Eine Quantifikation der Genexpression von *SpETHE1* mittels qPCR zeigte keinerlei Unterschiede zwischen SP050 und SP011, wodurch eine direkte Beeinflussung der Diquat Resistenz durch dieses Gen als unwahrscheinlich erscheint. Eine Messung der Expression von Genen in unmittelbarer Nähe zu *SpETHE1* zeigte eine verminderte Expression der *DIENELACTONE HYDROLASE* (*SpDLH*) und des *STARCH-BRANCHING-ENZYME 3* (*SpSBE3*) in SP050 verglichen mit SP011. Zusammenfassend wurden unterschiedliche Akkumulationskinetiken des Herbizids sowie antioxidative Stressantworten als ursächlich für die observierte Variation von Diquat Resistenzen ermittelt. Hierbei scheinen antioxidative Mechanismen einen kurzfristigen Schutz gegen Diquat-induzierten oxidative Stress zu vermitteln, bevor Transport-assoziierte Mechanismen ein langfristiges Überleben unter Diquat Exposition vermitteln. Weiterhin assoziierte die Studie Gene mit Bezug zu Stressantworten (*SpETHE1*, *SpDLH* and *SPGBPL2*) und Stärkeabbau (*SpSBE3*) mit Diquat Resistenz.

### 3.1.3 Statement of Contribution

In this project, Martin Höfer planned all experiments together with his supervisor Shuqing Xu. Together with Samuel Wink and Yangzi Wang, Martin Höfer conducted all toxicity studies. The analysis of SOD activity was done by Martin Höfer. Together with Martin Schäfer, Martin Höfer extracted and quantified antioxidants and diquat in plant tissue. Furthermore, Martin Höfer conducted all analyses, prepared all figures, and wrote the first draft of the manuscript. All co-authors provided suggestions for improving the content of the manuscript.

**Abstract:** Understanding non-target-site resistance (NTSR) to herbicides represents a pressing challenge as NTSR is widespread in many weeds. Using giant duckweed (*Spirodela polyrhiza*) as a model, we systematically investigated genetic and molecular mechanisms of diquat resistance, which can only be achieved via NTSR. Quantifying the diquat resistance of 138 genotypes, we revealed an 8.5-fold difference in resistance levels between the most resistant and most susceptible genotypes. Further experiments suggested that diquat uptake and antioxidant-related processes jointly contributed to diquat resistance in *S. polyrhiza*. Using a genome-wide association approach, we identified several candidate genes, including a homolog of dienelactone hydrolase, that are associated with diquat resistance in *S. polyrhiza*. Together, these results provide new insights into the mechanisms and evolution of NTSR in plants.

**Keywords:** non-targeted-site herbicide resistance; diquat; *Spirodela polyrhiza*; duckweed; GWAS; dose–response measurements

## 1. Introduction

More than 500 unique cases of herbicide resistance have been discovered worldwide [1]. Many of these herbicide resistance cases are caused by genetic changes other than the target site and are therefore referred as non-targeted-site resistance (NTSR) cases [2]. Since many NTSR cases constitute complex and polygenic traits, our current understanding of the evolution and mechanism of NTSR remains limited.

Due to their lack of target site resistance mechanisms, bipyridinium herbicides, such as diquat and paraquat, constitute an ideal system for deciphering the genetic basis of non-target-site resistance mechanisms. These herbicides act by diverting electrons from the photosystem I (PSI), thereby competing with ferredoxin for its binding place on PSI [3,4]. Upon electron acceptance from PSI, they transfer one electron to molecular oxygen, generating superoxide anions. The reactive oxygen species (ROS) produced by this Mehler-like reaction lead to the destruction of thylakoid membranes and a decrease in the photosynthesis rate of the plant, which ultimately causes cell death by the induction of apoptosis [5]. With the widespread usage of bipyridinium herbicides for weed and algae control in agriculture and aquaculture [6–9], numerous resistance cases have been reported since the 1980s [10,11]. Most of these resistance cases exhibited a cross-resistance between paraquat and diquat [6,10,12–14]. From a mechanistic point of view, the vast majority of these cases were due to the vacuolar sequestration/chloroplast exclusion of the herbicide [13,15–19], an increased activity of the plant’s antioxidant radical scavenging system [20,21], or an intracellular-uptake-associated mechanism [6,22].

Most of the known herbicide resistance mechanisms are also shown to be involved in stress responses to environmental factors such as salinity [23,24], oxidative stress [24], heavy metal exposure [25], and cold stress [24]. Most prominently, ABC transporters, a class

of proteins involved in various stress responses, such as those to drought [26], exposure to heavy metals [27], and pathogens [28], are involved in paraquat resistance [25,29]. These findings suggest that NTSR might have a pleiotropic origin from stress response or secondary metabolite pathways, thus explaining the short evolutionary time scale between the commercialization of herbicides and the appearance of resistant weed species. Yet, the underlying genetic principles remain poorly understood for many cases of bipyridinium herbicide resistance.

Here, we used giant duckweed *Spirodela polyrrhiza* (L.) Schleid. (Arales: Lemnaceae) as a model system to study the mechanisms of diquat resistance. Because of their high susceptibility towards bipyridinium herbicides [30], their small body, and fast clonal reproduction [31], duckweeds are often used for toxicological studies on herbicides. Among duckweeds, *S. polyrrhiza* has the smallest genome size and low genetic variation [32,33]. The available large genetic diversity panel and re-sequencing data on *S. polyrrhiza* will also enable the identification of genetic mechanisms using a genome-wide association (GWA) approach. In this study, we focused on two main questions: (1) To what extent do *S. polyrrhiza* genotypes vary in terms of their diquat resistance levels? (2) What are the underlying molecular and genetic mechanisms of diquat resistance?

## 2. Results

### 2.1. Intraspecific Variations in Diquat Resistance in *S. polyrrhiza*

As the intra-specific variations in resistance are dependent on the applied diquat concentration, we used a stepwise approach to select the diquat concentration for screening. First, we used two randomly selected genotypes to perform a dose–response curve in *S. polyrrhiza*. The results suggested that the EC10 and EC90 values for inhibiting FW (fresh weight) biomass in *S. polyrrhiza* are ~1.8 nM and ~11.1 nM, respectively. Measuring the inhibition of the relative growth rate of the frond number, we obtained EC10 and EC90 values of ~2.2 nM and ~53.0 nM, respectively (Figure A1, Table A1). We then screened diquat resistance among 19 genotypes using 5 and 10 nM of diquat. We found the broad-sense heritability of diquat resistance to be higher at 10 nM ( $H^2 = 0.98$ ) than at 5 nM ( $H^2 = 0.90$ ). Furthermore, several genotypes showed hormetic effects at 5 nM of diquat concentration, whereas at 10 nM, we found a clear inhibition ranging from 22% to 84% across all genotypes (Figure A2). Therefore, we chose 10 nM as the concentration for screening diquat resistance among 138 genotypes.

Among the screened genotypes, diquat resistance varied significantly, either estimated based on the RGR (relative growth rate) of the frond number, the RGR of the frond area, or the decrease in biomass (FW) (Figure A3). Of all the quantified parameters, the RGR of the frond number was the most reproducible for quantifying diquat resistance (Figure A4). We did not detect significant differences in diquat resistance between the four genetic populations of *S. polyrrhiza* (Tukeys HSD) identified using genome-wide markers (Figure A5). To further validate the variation in diquat resistance in our genotype accession, we performed dose-response experiments and estimated the EC50 values of the eight most resistant and eight most susceptible genotypes identified in the screening experiment (Table A2). The estimated EC50 value of the most resistant genotype (SP050, registered four-digit code: 0090) is 8.5-fold higher than that of the most susceptible genotype (SP011, registered four-digit code: 9242) (Figure 1 and Table A2). The differences in diquat resistance between SP050 and SP011 are also reflected by the decrease in two chlorophyll fluorescence parameters:  $F_v/F_m$  and  $F_v'/F_m'$ , in response to diquat. During the first 8 h of diquat treatment, SP050 has a much slower decay of  $F_v/F_m$  and  $F_v'/F_m'$  than SP011 (Figure 1C,D). Together, these results suggest that diquat resistance greatly varied among different genotypes of *S. polyrrhiza*.

**Figure 1.** Comparison of growth kinetics of the most resistant genotype SP050 and the most susceptible genotype SP011 under diquat treatment (A) *S. polyrhiza* genotypes SP011 and SP050 grown under various diquat concentrations for 8 days. (B) Dose-response curves depicting the mean IE values with their corresponding standard errors calculated from three biological replicates for various diquat concentrations. We used the UCRS4c hormetic model from the drc R-package to estimate the EC50 values. The predicted functions used to derive this value were drawn as colored lines. (C,D) The development of the chlorophyll fluorescence parameters Fv/Fm (C) and Fv'/Fm' (D) are shown over time. The data points constitute mean values from three biological replicates; error bars indicate  $\pm$  standard error, and different significance levels were marked with asterisks: \*— $0.05 \geq p\text{-adjust} > 0.01$ , \*\*— $0.01 \geq p\text{-adjust} > 0.001$ , \*\*\*— $p\text{-adjust} < 0.001$  (linear mixed effect model, Tukeys HSD).

## 2.2. Changes in Diquat Uptake and Antioxidant Capacity Contribute to Diquat Resistance

We compared the diquat uptake and antioxidant capacities among different genotypes to understand the molecular mechanisms of variations in diquat resistance. We found that diquat concentration in whole plants significantly correlates with inhibition effects, suggesting that reduced diquat uptake capacity increases diquat resistance (Figure 2A). However, the diquat concentration in frond tissue might be lower in highly resistant genotypes due to their larger biomass accumulation compared to susceptible genotypes after the 7 days of bioassay. To address this issue, we further compared the diquat uptake kinetics between SP050 and SP011 within 48 h, during which diquat did not affect plant biomass considerably. The results showed that SP011 accumulated significantly more diquat than SP050 after 24 h (Figure 2B), indicating their differences in diquat uptake capacity. A comparison of the diquat concentration between root and frond tissue suggested that roots have an approximately three-fold higher diquat concentration than fronds (Figure 2C).

However, differences in diquat uptake between SP011 and SP050 were likely not due to their differences in root/frond diquat concentration ratio, which are similar between the two genotypes (Figure 2C). A measurement of the medium concentration of diquat did not reveal large fluctuations in cultures of SP050 and SP011 within a period of 7 days (Table A3). Due to the high stability of diquat in plant tissue and medium samples, the measured uptake kinetics are unlikely to be confounded by degradation processes.

**Figure 2.** Uptake and translocation mechanisms of diquat. **(A)** The diquat resistance calculated based on the inhibition of the RGR of the frond number is significantly correlated (F-test) with the diquat tissue concentration of 137 genotypes. **(B)** After 24 and 48 h of diquat exposure, SP011 accumulated significantly more diquat than SP050. \*— $0.05 \geq p\text{-adjust} > 0.01$ , \*\*— $0.01 \geq p\text{-adjust} > 0.001$  (two-sided Student's *t*-test). **(C)** Both genotypes showed an approximately three-fold higher concentration of diquat in root tissue compared to frond tissue. No significant difference between the two genotypes was found (two-sided Student's *t*-test). The diquat tissue concentration was measured after 24 h of diquat exposure.

We then measured the antioxidant capacity by quantifying the glutathione and ascorbate content levels among eight *S. polyrhiza* genotypes. Glutathione and ascorbate play a

central function in protecting the plant from oxidative stress via the Asada–Halliwell–Foyer cycle (Figure 3A), which controls the redox hub by detoxifying superoxide anions generated by diquat. The quenching process of ROS occurs through the synergistic action of several enzymes, including the superoxide dismutase (SOD) via the conversion of the reductive metabolites AsA and GSH to their oxidized counterparts (Figure 3A), dehydroascorbate (DHA) and oxidized glutathione (GSSG), respectively. Therefore, we used the activity of SOD together with the ratios of AsA/DHA and GSH/GSSG as proxies to estimate antioxidant stress responses to diquat [23,24,34,35]. Diquat exposure decreased the GSH/GSSG and AsA/DHA levels in SP011 but not in SP050 (Figure 3B,C). For SP011, both ratios reached a minimum after 4 h of diquat treatment, followed by a recovery to their initial value after 24 h. The decline in the ratios was mainly reflected by a decrease in GSH and AsA concentrations in plant tissue (Figure A6). Additionally, we found a significant correlation between diquat tissue concentration and GSH/GSSG levels (Figure A7A) but not AsA/DHA levels (Figure A7B). However, the GSH/GSSG and AsA/DHA values were not correlated with resistance levels (Figure A7C,D). The enhanced maintenance of antioxidant ratios in SP050 is also reflected by the genotype's elevated SOD activity under diquat treatment over SP011 (Figure 3D). Together, these data suggest that SOD activity under diquat treatment is correlated with resistance levels to diquat (Figure A8A). However, no such association was observed for the constitutive SOD activity (Figure A8B).

### 2.3. Genetic Basis of Diquat Resistance in *S. polyrhiza*

To identify the genetic basis of diquat resistance, we applied a GWA approach using both the single-nucleotide polymorphisms (SNPs) and structure variations (SVs) that were identified in our previous study [37]. Among all 42,462 SNPs, only one synonymous SNP (C to T) located within the coding sequence of the guanylate-binding-protein-like 2 *SpGBPL2* (SpGA2022\_050909) showed a significant association with diquat resistance quantified based on FW only (Figures A9 and A10, Table A4). Among the 842 SVs, we found that a 94 bp deletion located in the seventh intron of the mitochondrial sulfur dioxygenase *SpETHE1* (SpGA2022\_053619) is associated with diquat resistance quantified based on all growth parameters (Figures 4A–C and A11, Table A5). Genotypes that are homozygous at the deletion locus were significantly more resistant to diquat than heterozygous genotypes or genotypes lacking the deletion. Also, heterozygous genotypes were on average more resistant than genotypes lacking the deletion (Figure 4D). In addition, we found a 184 bp deletion within the fourth exon and the fourth intron of the lipoxygenase 2.1 *SpLOX2.1* (SpGA2022\_008887) (Figures 4B, A11 and A12, Table A5) and a 56-bp deletion in an intergenic region (Figures 4C and A11, Table A5) that is ~60 Kb far from the next open reading frame to be associated with diquat resistance. However, the 184 bp and 56 bp deletions are specific to only one of the growth parameters that were used for quantifying resistance effects.

To further validate the association between the 94 bp deletion in the *SpETHE1* intron and diquat resistance, we amplified the deletion region using PCR in the genomes SP050 and SP011. These two genotypes showed different levels of diquat resistance. The results confirmed that SP050 is homozygous for the identified deletion and that SP011 is lacking the deletion completely (Figure A13A). We then aimed to examine whether the deletion affected the expression or splicing of *SpETHE1* using qPCR. To this end, we conducted a time-course experiment and analyzed the expression and splicing of *SpETHE1* in the roots and fronds, respectively. We could not find any differences in the splicing pattern between SP050 and SP011, neither for the control nor for the diquat-treated samples (Figure A13B). We found that *SpETHE1* expression was elevated in the root tissue relative to the frond tissue, approximately by a factor of three in both genotypes (Figure A14B). However, under control conditions and within 4 h of diquat treatment, the expression levels were similar between SP011 and SP050 (Figures 5 and A14). After 72 h of diquat treatment, in the fronds, *SpETHE1* expression was 21% lower in SP050 compared to SP011, and it showed similar expression in the roots (Figures 5A and A14A). The differential expression is likely due to the differences in diquat uptake between the two genotypes.

**Figure 3.** (A) Foyer–Asada–Halliwell cycle according to Noctor and Foyer, 1998 [36]. Enzymes are highlighted by red margins. Metabolites analyzed in this study are underlined. SOD converts superoxide anions to  $H_2O_2$ . Through oxidation of AsA,  $H_2O_2$  is degraded to  $H_2O$  by APX. AsA is regenerated by oxidation of GSH to GSSG. The latter is reconverted to GSH by GR, consuming NADPH. SOD—superoxide dismutase, APX—ascorbate peroxidase, MDHAR—monodehydroascorbate reductase, DHAR—dehydroascorbate reductase, GR—glutathione reductase. The time course of mean GSH/GSSG (B) and AsA/DHA (C) ratios of four to five replicates with their respective standard errors are shown for SP050 and SP011. SP050 exhibited a significantly increased GSH/GSSG ratio over SP011 after 4 h of diquat treatment and an increased AsA/DHA ratio after 4, 8, and 24 h of diquat treatment (unpaired two-sided Student’s *t*-test). (D) Mean SOD activity after 1-day incubation at 10 nM of diquat or control conditions for three biological replicates  $\pm$  standard error. Genotype SP050 exhibited a significantly higher SOD activity than SP011 after 24 h of diquat exposure. \*— $0.05 \geq p\text{-adjust} > 0.01$ , \*\*— $0.01 \geq p\text{-adjust} > 0.001$ , \*\*\*— $p\text{-adjust} < 0.001$  (two-sided Student’s *t*-test).

**Figure 4.** (A–C) Manhattan plots from a GWAS conducted on structure variations, highlighting the diquat resistance-associated 94 bp deletion in *SpETHE1*. All significant markers (Wald test) were highlighted as green dots. The Bonferroni corrected significance threshold (red line) at  $p < 0.05$  is  $5.94 \times 10^{-5}$ . The GWAS was conducted using normalized inhibition effects calculated based on frond number (A), frond area (B), and fresh weight (C). (D) Box plot of mean values of the norm. IE RGR of

the frond number of genotypes carrying the respective alleles. On average, genotypes homozygous for the deletion were more resistant to diquat than heterozygous genotypes or genotypes without the deletion.  $** - 0.01 \geq p\text{-adjust} > 0.001$ ,  $*** - p\text{-adjust} < 0.001$  (Tukeys HSD). Heterozygous genotypes exhibited a greater mean resistance than genotypes without deletion. (E) Gene structure of *SpETHE1* with the 94 bp deletion in the seventh intron highlighted as a red box.

**Figure 5.** Relative transcript abundance of candidate genes in the frond tissue of *S. polyrhiza*. Mean values of five biological replicates are shown with their respective standard errors. (A) *SpETHE1* expression in SP050 and SP011 relative to its mean expression in SP011 without diquat treatment (Ctrl) or treated with diquat for 4 h and 72 h. After 72 h, *SpETHE1* was less expressed in SP050 than in SP011 (two-sided Student's *t*-test). (B) The location of *SpDLH*, *SpTRB1*, *SpALA2*, *SpSBE3* and the deletion in *SpETHE1*. The deletion is depicted as a red line. Transcript abundance of *SpDLH* (C), *SpTRB1* (D), *SpALA2* (E), and *SpSBE3* (F) in SP050 relative to their mean expression in SP011. The transcript abundances of *SpDLH* and *SpSBE3* are lower in SP050 than in SP011 (two-sided Student's *t*-test).

Because the genome of *S. polyrhiza* is compact and cis-regulatory elements can be located further away from the gene, we examined the expression of four genes located near *SpETHE1*: *SpDLH* (SpGA2022\_012161), *SpALA2* (SpGA2022\_053617), *SpSBE3* (SpGA2022\_053621), and *SpTRB1* (SpGA2022\_012163) (Figure 5B–F and Figure A14). Among them, the expression of *SpDLH*, the start codon of which is located 9.6 Kb downstream of the deletion (Figure 5B), is ~67% lower in the root tissue of SP050 compared to SP011 (Figure A14C). In the frond tissue, the expression was ~45% lower in SP050 compared to SP011 (Figure 5C). *SpDLH* is a homolog of diene lactone hydrolase, which is involved in the degradation of xenobiotics such as chlorocatechol [38] and might be linked to apoptotic processes as well [39]. In addition, the expression of *SpSBE3*, the start codon of which is located 7.7 Kb from the deletion, is 21% lower in the frond tissue of SP050 than in SP011 (Figure 5C). The expression of the other two genes was not different between SP050 and SP011.

### 3. Discussion

Here, we investigated the diquat resistance in *S. polyrhiza* using the worldwide diversity panel and identified gene candidates associated with the resistance. We found that the levels of resistance varied among genotypes by a factor of 8.5, likely due to the combination of changes in diquat uptake kinetics and antioxidant capacity. We used a GWAS approach to show that several candidate genes involved in metabolic processes or stress responses to biotic or abiotic factors are likely associated with diquat resistance.

Our results did not reveal any gene candidates with a transporter or carrier function that might have caused the observed differences in diquat uptake. Yet, since bipyridinium herbicides were also shown to bind to plant cell walls, restricted herbicide movement into the apoplast might not be exclusively explained through the plasma membrane transporter but also by the genotype's cell wall composition as shown in paraquat-resistant biotypes of *Hordeum glaucum* (L.) Steud. (Poales: Poaceae) and in *Rehmannia glutinosa* (Gaertn.) Steud. (Lamiales: Orobanchaceae) [13,40]. Since we did not check for uptake differences on apoplast and protoplast levels separately, we cannot rule out the involvement of such extracellular movement barriers in diquat uptake. On a systemic level, increased retention of diquat in root tissue seems unlikely to explain differences in resistance levels since the root/frond ratio of the diquat concentration was similar across resistance levels. Alternatively, the observed difference in the diquat concentrations can be due to different capacities in metabolizing the herbicide.

From a physiological point of view, the increased diquat resistance of SP050 was characterized by an increased SOD activity and stable antioxidant ratios under diquat exposure compared to susceptible genotypes. Such genotypic-specific changes in AsA/DHA ratios were previously related to differences in SOD activity [35]. Since the GSH/GSSG ratio and diquat tissue concentration were significantly correlated after 24h of diquat exposure, some of the observed differences in antioxidant ratios might be influenced by diquat uptake kinetics as well. This suggests that diquat resistance in *S. polyrhiza* is likely facilitated by a synergistic involvement of uptake-related and antioxidant processes. Related to this, it was proposed that antioxidant processes only provide short-term protection against herbicide-mediated oxidative stress before more potent mechanisms such as sequestration or reduced uptake of the herbicide secure the long-term survival of resistant genotypes [41], which might explain why diquat-caused changes in the antioxidant ratios were only transient across different resistance levels.

From a genetic perspective, a 94-bp intronic deletion in *SpETHE1* was the only marker associated with several resistance parameters. Since we did not find significant differences in gene expression or splicing patterns associated with the deletion, the direct functional involvement of *SpETHE1* in diquat resistance seems unlikely. Yet, the differential expression of *SpDLH* and *SpSBE3*, two genes downstream of *SpETHE1*, as a potential consequence of the deletion, might suggest the involvement of long-distance gene regulation mechanisms. Such regulatory mechanisms seem to be more common in plant species with large or middle-sized genomes, such as *Zea mays* L. (Poales: Poaceae) [42,43] or *Oryza sativa* L.

(Poales: Poaceae) [44] than in species with small genomes like *Arabidopsis thaliana* (L.) Heynh. (Brassicales: Brassicaceae) [45,46]. Yet, enhancement of transcription through chromatin looping was also shown to be established by introns [47], which might be a process more common in species with compact genomes that lack long intergenic sequences like *S. polyrhiza*.

Many homologs of our candidate genes were involved in various metabolic or stress response pathways. Whereas GBPLs and lipoxygenase like *SpLOX2.1* are involved in response mechanisms to pathogen infection [48–50], *SBE3* is involved in starch metabolism [51]. *DLH* functions in xenobiotic degradation [38,52] and apoptosis [39]. Their association with diquat tolerance suggests a pleiotropic function in herbicide resistance for these genes.

The conceptual connection of pleiotropic gene function to bipyridinium herbicide resistance was first established in *Conyza canadensis* (L.) Cronquist. (Asterales: Asteraceae) [53], where resistance to paraquat was inherited by a single gene that controls the regulation of multiple antioxidant enzymes [53]. In *Avena fatua* L. (Poales: Poaceae), multiple genes with pleiotropic functions that were involved in xenobiotic catabolism, redox maintenance, secondary metabolite pathways, and stress response pathways were differentially expressed at constitutive levels between resistant and susceptible biotypes [54]. These findings suggest that resistant genotypes benefit from a faster upregulation of their stress response when they experience herbicide exposure [54,55]. Since herbicide treatments trigger a systemic stress response, it has been argued that sub-lethal doses of herbicides will select genotypes with a constitutive upregulation of stress response-associated genes [55]. Yet, since many of our genotypes have likely never experienced direct selection through sub-lethal doses of diquat, this concept is only partially suitable for explaining the observed variation in diquat resistance. Alternatively, non-targeted-site resistance to herbicides can also be induced by heterogeneous environments [56], suggesting that the observed resistance to diquat in *S. polyrhiza* also might have evolved from a simultaneous adaptation to multiple environmental stress factors [57].

Taken together, this study paved the foundation for understanding the evolution of diquat resistance in *S. polyrhiza*. Further studies validating the function and mechanisms of the identified candidate genes will provide further insights into the evolution of herbicide resistance in plants and help develop more sustainable weed management strategies.

## 4. Materials and Methods

### 4.1. Plant Material and Cultivation Procedure

For pre-cultivation, we propagated plant material of *S. polyrhiza* in Erlenmeyer flasks for 14 days before each assay. For all assays and pre-cultivations we grew our *S. polyrhiza* genotypes in N-medium [58] at 26 °C, with 135  $\mu\text{mol photons}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$  of light per day, a light/dark rhythm of 16h/8h and 50% humidity (GroBanks, model BB-XXL.3+cLED, CLF Plant Climatics, Wertingen, Germany) if not stated otherwise. Before each assay, we sterilized all of the analyzed genotypes via a combined protocol involving Klorix and Cefotaxime [59]. For all of the conducted assays, we grew the plants in plastic beakers (Verpackungsbecher PP, transparent, round, 250 mL, Plastikbecher.de GmbH, Giengen, Germany) filled with 150 mL N-medium (control conditions). We covered the cultures using perforated lids to allow air exchange. For the herbicide treatments, we supplemented the N-medium with the indicated concentration of diquat (Diquat-dibromide monohydrate, CAS:6385-62-2, Supelco, St. Louis, MO, USA). For all diquat measurements, the herbicide concentration is always expressed as the concentration of diquat-dibromide. Diquat was always applied as an aliquot from aqueous stocks. At the starting point of each experiment, we added fronds as colonies to the medium. If not stated otherwise, we triplicated each condition and genotype in all experiments.

### 4.2. Quantification of Diquat Toxicity

We expressed the diquat resistance of each genotype based on the changes in the fitness parameter relative growth rate (RGR) of frond number and frond area as well as

the inhibition of fresh weight (FW) relative to an untreated control. To estimate the first two parameters, we counted the frond number and determined the surface area overgrown with fronds for each culture at the beginning and end of each assay. To this end, we took a picture of each culture at the beginning and end of each toxicity assay. To quantify the frond area, we added a reference stone with a black square of an edge size of 1 cm to each culture. At the endpoint of the cultivation, we harvested the plant material, dried it briefly with tissue paper, and stored it in pre-scaled reaction tubes to determine the FW. The procedure mentioned above applies to all toxicity assays if not stated otherwise. Based on these data, we calculated the RGR using a published method [31]:

$$RGR = \frac{\ln NE - \ln N0}{t}$$

where  $NE$  is the frond number/area at the endpoint of the toxicity test and  $N0$  is the frond number/area at the starting point of the toxicity test.

We expressed the inhibition of the herbicide on the growth of the genotypes as an inhibitory effect ( $IE$ ) defined by the following formula for all fitness parameters mentioned above:

$$IE = \frac{M-X}{M} \times 100$$

where  $M$  is the mean of an untreated control and  $X$  is the mean of the treatment.

#### 4.2.1. Determination of Screening Concentration

First, we aimed to identify a suitable diquat concentration that affects the growth in most of the genotypes. To make a rough estimate, we applied a diquat concentration range of 2 nM to 500 nM to two randomly selected genotypes, SP035 (registered four-digit code: 0109) and SP077 (registered four-digit code: 9508). For each replicate, we inoculated ten fronds at the start of cultivation and harvested the plant material after 10 days of cultivation. For each concentration, we quantified the growth inhibition as the  $IE$  of the FW and the RGR of the frond number. To estimate a screening concentration, we calculated the  $EC_{10}$  and  $EC_{90}$  values for both parameters and genotypes using the  $EC$  function from the “drc” R-package [60,61]. Based on the information obtained from this experiment, we further narrowed down the range of potential screening concentrations by testing the inhibition of 19 genotypes to 5 nM and 10 nM of diquat. Our criterion for choosing a suitable screening concentration was that no hormetic effects were visible for any of the 19 genotypes. To avoid the overgrowth of cultures, we decreased the cultivation time to 7 days and inoculated only six fronds at the starting point of the experiment. We quantified diquat resistance based on the  $IE$  of the RGR frond number ( $IE$  of RGR frond number), the  $IE$  of the RGR frond area ( $IE$  of RGR frond area) and the  $IE$  of the fresh weight ( $IE$  of FW). We further estimated the broad-sense heritability of diquat resistance at 5 and 10 nM according to a published method [62] using the  $H2cal$  function of the *inti* R-package [63].

#### 4.2.2. Diquat Resistance Screening

We assayed 138 genotypes in five batches, each encompassing 23 to 35 genotypes, regarding their growth inhibition at a diquat concentration of 10 nM for 7 days. A list of all screened genotypes is provided in the Supplementary Materials (Table S1). At the beginning of the cultivation, we inoculated six fronds in each culture. To control for batch effects, we cultivated genotype SP028, which continuously served as an internal standard throughout all batches. We then normalized the inhibition of all genotypes to that of SP028 in the respective batch. We used these normalized values of the  $IE$  of RGR the frond number (norm.  $IE$  RGR of frond number) and area (norm.  $IE$  of RGR frond area) and the  $IE$  of the FW (norm.  $IE$  of FW) to identify the most resistant and susceptible genotypes.

#### 4.2.3. Dose–Response Measurements

To quantify the variation in diquat resistance levels in our 138-genotype accession, we estimated the half maximal effective concentration ( $EC_{50}$ ) values for the eight most resistant and the eight most susceptible genotypes identified in our resistance screening. We applied a concentration range from 0.5 nM to 100 nM of diquat to a population of six fronds at the starting point of the assay. The duration of the toxicity test was 8 days.

To correct for the occurrence of hormetic effects, we calculated all dose–response curves using the *drc* R-package, applying the hormetic Cedergreen–Ritz–Streibig model UCRS.4c, which has previously been used in toxicity tests of herbicide formulations on duckweed species [64]. In contrast to normal logistic models, which are strictly monotonous functions, the UCRS.4c model takes stimulatory effects, that are caused by hormesis into account [64]. Therefore, the UCRS.4c model estimates the potency of the herbicide via a lower bound on the ED50 value [64]. Since the hormetic effects were minimal in all cases, the lower bound on ED50 provides a close approximation of the EC50. Therefore, we refer to the lower bound on ED50 as an estimate of EC50 in this manuscript.

#### 4.3. Chlorophyll Fluorescence Measurement

We evaluated diquat resistance on a physiological level, measuring the decay of the chlorophyll fluorescence parameters  $F_v/F_m$  and  $F_v'/F_m'$  in response to high levels of diquat. The  $F_v/F_m$  ratio indicates the decrease in the quantum yield of linear electron flow through PSII [65] and the  $F_v'/F_m'$  ratio is an estimate of the maximum quantum yield of PSII in a light-adapted state [66]. We quantified  $F_v/F_m$  and  $F_v'/F_m'$  for the previously identified four most resistant (R) and four most susceptible genotypes (S). For this, we acclimated all of the plant cultures at 26 °C at 110  $\mu\text{mol photons}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$  of light per day and a light/dark rhythm of 16 h/8 h (Percival, model AR-41L3, CLF Plant Climatics) for two days before measurement. We used 12-well plates (Nunc, Roskilde, Denmark) filled with 6 mL of N-medium containing 40  $\mu\text{M}$  of diquat for herbicide exposure of the plant material. Each well was inoculated with a duckweed colony composed of three to four fronds. Each genotype was analyzed with three biological replicates for each time point. For each replicate, three areas of interest were defined. We chose durations of 0 min, 30 min, 1 h, 2 h, 4 h, 8 h, 12 h, and 24 h as endpoints for the incubation. We conducted fluorescence measurements using an I-PAM system (M-series, MAXI version, Heinz Walz GmbH, Effeltrich, Germany), applying all settings published previously for chlorophyll fluorescence measurements in *Lemna minor* L. (Arales: Lemnaceae) [67]. For dark adaptation, we incubated our samples in the dark for ten min before the saturation pulse. After recording  $F_v/F_m$ , we adapted the plants to actinic light at 84 PAR (photosynthetically active radiation) for 10 min, before measuring the  $F_v'/F_m'$  ratio.

#### 4.4. Superoxide Dismutase Activity

We measured SOD activity for the four most susceptible (S) and four most resistant (R) genotypes identified in our dose–response experiment. To determine the superoxide dismutase (SOD) activity from the plant material, we cultivated five colonies of each genotype under 10 nM of diquat or under control conditions for 24 h. Next, we suspended 10 mg (FW) of plant material from each sample in 500  $\mu\text{L}$  of 0.01 M MOPS buffer (Carl Roth, Karlsruhe, Germany) at pH 7.2. We homogenized the suspension by pulsed mixing for 5 s and centrifuged each sample at  $14,000\times g$  for 1 min before analysis. For the quantification of the SOD activity, we diluted 150  $\mu\text{L}$  of supernatant 1:4 in MOPS buffer pH 7.2. We measured SOD activity following the instructions of the SOD determination kit (Product 19160, SOD Assay Kit, Sigma-Aldrich, St. Louis, MO, USA). To determine the protein concentration, we diluted the supernatant 1:2 in MOPS buffer at pH 7.2 and analyzed the samples according to the manufacturer's instructions using the Rapid Gold BCA Protein Assay Kit (Thermo Fisher Scientific, Waltham, MA, USA). We standardized SOD activity to the measured protein content. To check for the involvement of SOD activity in diquat resistance, we further correlated the SOD activity with our estimates of EC50 values.

#### 4.5. Ascorbate and Glutathione Measurements

To measure the impact of diquat exposure on shifts in the concentration ratios of ascorbate (AsA) to dehydroascorbate (DHA) and reduced (GSH) to oxidized glutathione (GSSG), we cultivated 30 fronds from each R and S genotype for 4, 8 and 24 h under 10 nM of diquat. We grew the control samples for 24 h in N-medium without diquat. For each

genotype and measurement point, we made five biological replicates. At the endpoint of the assay, we harvested all of the plants, dried them with tissue paper, transferred them into pre-scaled reaction tubes, and froze them immediately in liquid nitrogen. We stored all of the samples at  $-80\text{ }^{\circ}\text{C}$  until analysis. We extracted antioxidants from samples of 20 mg FW each with 250  $\mu\text{L}$  of 5% (*w/v*) metaphosphoric acid (Carl Roth). The extracts were diluted 1:10 with 5% (*w/v*) metaphosphoric acid containing 1.11  $\mu\text{g}/\text{mL}$  of isotope-labeled GSH (Glutathione-Glycine- $^{13}\text{C}_2,^{15}\text{N}$ , Sigma-Aldrich) (labGSH). The further steps of the extraction protocol are based on a method published previously with the modifications listed below [68].

We analyzed all of the antioxidants via LC-MS. For separation, we used a Nexera X3 UHPLC system (Shimadzu, Kyoto, Japan) equipped with a Nucleodur Sphinx RP column ( $250 \times 4.6\text{ mm}$ , 5  $\mu\text{m}$ , Macherey-Nagel, Düren, Germany) and a Nucleodur Sphinx RP EC 4/3 guard column (5  $\mu\text{m}$ , Macherey-Nagel) maintained at  $25\text{ }^{\circ}\text{C}$ . For the mobile phase, we used an aqueous solution of 0.2% (*v/v*) formic acid, 0.05% (*v/v*) acetonitrile as buffer A, and acetonitrile as buffer B. For elution, we applied a gradient mode using the following program: 0.0 min/2% B, 3.5 min/2% B, 5.0 min/100% B, 8.0 min/100% B, 8.2 min/2% B, 12.5 min/2% B at a constant rate of 1 mL/min. The injection volume was 1  $\mu\text{L}$  of extract per sample. For quantification we used an LC-MS/MS-8060 (Shimadzu) with an electrospray ionization source with the following parameters: nebulizing gas flow: 3 L/min, heating gas flow: 10 L/min, drying gas flow: 10 L/min, interface temperature:  $350\text{ }^{\circ}\text{C}$ , DL temperature:  $250\text{ }^{\circ}\text{C}$ , heat block temperature:  $400\text{ }^{\circ}\text{C}$ , CID gas flow: 270 kPa, interface voltage: 4000 V. GSH and labGSH were quantified in the positive ionization mode, all other metabolites were quantified in the negative ionization mode. We operated with a mass spectrometer in multiple reaction monitoring (MRM) mode using the following settings: Ch1: 308.09  $\rightarrow$  76.1  $m/z$  (CE  $-26\text{ V}$ ), Ch2: 308.09  $\rightarrow$  162.1  $m/z$  (CE  $-16\text{ V}$ ) for GSH, Ch1: 311.09  $\rightarrow$  181.95  $m/z$  (CE  $-11\text{ V}$ ), Ch2: 311.09  $\rightarrow$  165.2  $m/z$  (CE  $-14\text{ V}$ ) for labGSH, Ch1: 173.01  $\rightarrow$  113.20  $m/z$  (CE 10 V), Ch2: 173.01  $\rightarrow$  143.05  $m/z$  (CE 12 V) for DHA, Ch1: 175.02  $\rightarrow$  86.85  $m/z$  (CE 22 V), Ch2: 175.02  $\rightarrow$  115.05  $m/z$  (CE 13 V) for AsA and Ch1: 611.14  $\rightarrow$  305.85  $m/z$  (CE 24 V), Ch2: 611.14  $\rightarrow$  271.90  $m/z$  (CE 28 V) for GSSG. For all of the metabolites, Ch1 was used as the quantifier and channel Ch2 as the qualifier. We facilitated the quantification of GSH based on the internal standard labGSH. In the case of GSSG, AsA, and DHA, we quantified them using the internal standard and a conversion factor (CF) that was determined based on external standard curves ( $n_{\text{Analyte}} = n_{\text{labGSH}} \times \text{CF}$ ). The empirically determined CFs were 13.1 for AsA, 652.6 for DHA and 2.2 for GSSG.

#### 4.6. Diquat Measurement

To check the possibility of an involvement of transport-related mechanisms in diquat resistance, we quantified the diquat concentration in plant tissue for all R and S genotypes. To relate diquat resistance to tissue concentration, we extracted diquat from freeze-dried samples of 138 genotypes. We pooled all triplicates of the same genotype treated with diquat. Due to a sample being lost during diquat extraction, the total number of samples was reduced to 137. The extraction procedure follows a previously described method with minor modifications [69]. We homogenized the freeze-dried plant material (DW) in a tissue lyser (Qiagen, Venlo, The Netherlands) by adding two to three metal beads and shaking for 1 min at 25 Hz. We aliquoted 10 mg of the ground plant material in 96-well biotubes (catalog number: MTS-11-C, MTS-11-C-R, Axygen, New York, NY, USA) and resuspended each sample with 800  $\mu\text{L}$  of 40% (*v/v*) methanol, that was acidified with 0.0375 N HCl and contained 20 ng [ $^2\text{H}_4$ ]-diquat dibromide (03627-5 mg, Supelco) as an internal standard. We homogenized the samples in a tissue lyser (Qiagen) at 20 Hz for 10 min, followed by an incubation step at  $80\text{ }^{\circ}\text{C}$  for 15 min and a second homogenization step at 20 Hz for 10 min. After two centrifugation steps at  $2000 \times g$  for 20 min at  $4\text{ }^{\circ}\text{C}$ , we transferred the supernatant to a PCR plate for analysis. Due to the adhesion of diquat to glass surfaces, we did not use glass tubes throughout the whole extraction process. Before the measurement, we performed another centrifugation step at  $2000 \times g$  for 20 min at  $4\text{ }^{\circ}\text{C}$ .

Since tissue dilution effects caused by the higher propagation rates of resistant compared to susceptible genotypes in the diquat treatments might have confounded the correlation between diquat resistance and tissue concentration, we established an uptake kinetic for the R and S genotypes. We cultivated the genotypes in N-medium supplemented with 10 nM of diquat for 15 min, 30 min, 1 h, 2 h, 4 h, 8 h, 12 h, and 24 h. We triplicated each treatment, with each replicate containing 15 fronds growing in colonies. We extracted 2 mg of homogenized plant material (DW) applying the workflow described above but using only 200  $\mu$ L of extraction buffer containing 1 ng of the [ $^2\text{H}_4$ ]-diquat dibromide as the internal standard per sample.

We measured the diquat concentration in the root and frond tissue separately to look for tissue-specific translocation patterns. We cultivated the genotypes at 10 nM of diquat for 24 h. Each replicate consisted of 30 fronds growing as colonies. We dissected samples into the root and frond tissue for separate analysis. The extraction of each 2 mg of tissue per sample was performed as described in the previous paragraph.

To monitor changes in the diquat concentration of the medium, we cultivated R and S genotypes for 7 days at 10 nM of diquat. Each day, a medium sample of 400  $\mu$ L was taken from each replicate and immediately frozen in liquid nitrogen. After lyophilization, we resuspended the precipitate in 400  $\mu$ L extraction buffer containing 4 ng of [ $^2\text{H}_4$ ]-diquat dibromide. We then homogenized 300  $\mu$ L of the supernatant in a tissue lyser as mentioned above and continued with the extraction as described for plant tissue samples.

We analyzed the diquat via LC-MS. For separation, we used a Nexera X3 UHPLC system (Shimadzu) coupled to an LC-MS/MS-8060 with an Acclaim Trinity Q1 column (100  $\times$  2.1 mm, 3  $\mu$ m, Thermo Fisher Scientific) and a Trinity Q1 guard column (10  $\times$  2.1 mm, 5  $\mu$ m, Thermo Fisher Scientific) maintained at 30  $^\circ\text{C}$ . The injection volume of the sample was 0.5  $\mu$ L for all measurements. For the mobile phase, we used a buffer containing 75% (*v/v*) acetonitrile and 25 mM ammonium acetate with a pH adjusted to 5.0 with acetic acid in an isocratic mode at a flow rate of 0.4 mL/min. For quantification, we used an LCMS-8060 (Shimadzu) with an electrospray ionization source with the following parameters: nebulizing gas flow: 3 L/min, heating gas flow: 10 L/min, drying gas flow: 10 L/min, interface temperature: 300  $^\circ\text{C}$ , DL temperature: 250  $^\circ\text{C}$ , heat block temperature: 400  $^\circ\text{C}$ , CID gas flow: 270 kPa, interface voltage: 1000 V. The mass spectrometer operated in multiple reaction monitoring (MRM) mode using the following settings: Ch1: 183.09  $\rightarrow$  157.00 *m/z* (CE  $-20$  V), Ch2: 183.09  $\rightarrow$  130.10 *m/z* (CE  $-31$  V) for diquat and Ch1: 186.11  $\rightarrow$  158.00 *m/z* (CE  $-20$  V), Ch2: 186.11  $\rightarrow$  131.10 *m/z* (CE  $-33$  V) for [ $^2\text{H}_4$ ]-diquat. For this measurement channel, Ch1 was the quantifier and Ch2 the qualifier. To check for potential associations between the uptake of diquat or the diquat resistance and the antioxidant levels, we correlated the diquat tissue concentration after 24 h and the resistance levels with the GSH/GSSG and AsA/DHA levels.

#### 4.7. GWAS

To reduce the false positive signals due to clonality, we selected all sequenced genotypes from our 138 genotype accession and grouped them into 98 genets according to a recently published method [70]. From each genet the genotype with the highest sequencing coverage was selected as representative genotype. All of the analyzed genotypes are listed in the Table S1. We used the normalized IE of FW, frond number and frond area as input parameters for the GWAS. We conducted all GWAS on the 98 representative genotypes using an univariate linear mixed model [71] implemented in the vcf2gwas package [72]. We used structural variants (SVs) (>50 nucleotides) and SNPs as input for our GWAS analyses. All genotypic data for SNPs and SVs, as well as the annotation, were part of a recent publication [37] and can be found under [https://github.com/Xu-lab-Evolution/Great\\_duckweed\\_pogp](https://github.com/Xu-lab-Evolution/Great_duckweed_pogp) (accessed on 9 January 2024).

We formatted the genotype SV dataset as the input for vcf2gwas according to the published protocol [73]. Before analysis, we pruned our SNP and SV datasets using the PLINK package, which is integrated in the vcf2gwas platform, applying a window size

of 100 markers, a step size of 10 markers, and allowing a phased  $r^2$ -threshold of 0.33. We removed all SNPs and SVs with a minor allele frequency (MAF) of less than 5%, resulting in 842 SVs and 42,462 SNPs.

To estimate differences in diquat resistance on a population level, we sorted all genotypes into four genetic populations based on previously published information [37].

#### 4.8. RT-PCR Analysis of Splicing Pattern in *SpETHE1*

To validate the presence of the identified mutations in the most resistant (SP050) and the most susceptible genotype (SP011), we isolated genomic DNA from these *S. polyrhiza* genotypes using the DNeasy Plant mini kit (Qiagen) and genotyped them using primers 1\_ETHE1\_fwd and 2\_ETHE1\_rev (Table A6). The presence of the 94 bp deletion would yield a 705 bp product, whereas a wild-type sample would give a 799 bp product. The PCR program included an initial denaturation step at 95 °C for 3 min followed by 31 cycles of 95 °C—15 s, 60 °C—15 s, 72 °C—70 s with a single final elongation step at 72 °C for 5 min. We visualized the products on a 1% agarose gel.

To check whether *SpETHE1* (SpGA2022\_053619) shows different splicing patterns between SP050 and SP011, we cultivated 30 fronds of each genotype for 4, 8, and 24 h at a 10 nM diquat concentration. For each genotype, 30 fronds each were cultivated for 24 h in a medium without diquat were used as control. For all RNA sample preparations, we extracted <20 mg of FW aliquots using the InnuPREP RNA mini kit (Analytik Jena, Jena, Germany) and checked RNA integrity on a 1% agarose gel afterwards. We performed all cDNA synthesis reactions following the RevertAid First Strand cDNA synthesis kit (Takara, Shiga, Japan) using random hexameric primers to ensure cDNA synthesis from low-stability RNAs lacking polyA-tails. Next, we amplified fragments from the *SpETHE1* cDNA samples with the primers 3\_ETHE1\_fwd and 2\_ETHE1\_rev (Table A6), that bind on the fourth and ninth exon. The primers are flanking the intronic sequence carrying the deletion. Correct splicing is indicated by a fragment size of 330 bp. We carried out an amplification from genomic DNA using the same primer pair as the control, expecting a product of 1848 bp. The time program for amplification from cDNA template included an initial denaturation step at 95 °C for 3 min followed by 30 cycles of 95 °C for 15 s, 60 °C for 15 s, 72 °C for 30 s with a single final elongation step at 72 °C for 5 min. For amplification from genomic DNA, the duration of the extension step at 72 °C was increased to 150 s. We separated the products on a 2% agarose gel. For all amplifications, we used the PrimeSTAR HS DNA polymerase (Takara).

#### 4.9. RT- qPCR for Monitoring Gene Expression in Duckweed Tissue

We measured the expression differences in *SpETHE1* and genes in close distance to *SpETHE1* in SP050 and SP011. To analyze the diquat-induced differences in expression levels of *SpETHE1* in root and frond tissue separately, we cultivated 40 fronds from each genotype for 4 and 72 h at 10 nM of diquat. As a control, we cultivate 40 fronds from each genotype at N-medium without diquat for 24 h. We made five biological replicates for each genotype and treatment. Since *ETHE1* showed a potential circadian and diurnal regulation pattern [74,75], we always harvested the treated samples and controls at the same time of day. Root and frond tissue were collected from each culture separately. The root and frond tissues of the control cultures were also used to determine the constitutive expression levels of the flanking genes *SpDLH* (SpGA2022\_012161), *SpTRB1* (SpGA2022\_012163), *SpALA2* (SpGA2022\_053617), and *SpSBE3* (SpGA2022\_053621). We conducted all cDNA syntheses as described in the previous section but with oligo-dT primers instead of random hexameric primers. For all qPCR experiments, we quantified *SpETHE1* according to a previously published method [76] using the glycerin-aldehyde-3-phosphate dehydrogenase (*SpGAPDH*, SpGA2022\_054082) and alpha elongation factor one (*SpaEF*, SpGA2022\_005771) as reference genes. The primer sequences of the two reference genes were published previously [37].

We calculated the primer efficiencies based on a dilution series of cDNA templates (Table A7) and evaluated their specificity by loading the reaction mixtures on a 2% agarose gel. Before starting the RT-qPCR, we diluted all cDNA samples 1:100 in water. We carried out the RT-qPCR using a RotorGene Q system (Qiagen), using a master mix from the KAPPA SYBR FAST kit (Roche, Basel, Switzerland). For each gene and sample, we made three technical replicates. The time program for qPCR included an initial denaturation at 98 °C for 3 min followed by 40 cycles of 98 °C for 3 s of denaturation and 60 °C for 20 s of annealing/extension.

#### 4.10. Software and Statistics

We performed all statistical analyses using R version 4.2.0. We analyzed all of the pictures used to quantify the frond areas and numbers using ImageJ (version 1.53g) running on the Fiji platform. We accomplished the measurement of chlorophyll fluorescence using ImagingWinGigE version 2.47. For all LCMS measurements, we recorded the signals using LabSolutions version 5.97. We integrated peaks using Lab Solutions Insight version 3.5 SP2. We used the FSA package of R [77] to calculate the standard errors. For the statistical analyses of differences in chlorophyll fluorescence parameters, we applied the lme4 package [78] and the multcomp R packages [79] to implement a linear mixed effect model and a Tukeys post hoc test for multiple comparisons. For all other experiments involving the most resistant and most susceptible genotype, we compared mean values using the Student's *t*-test. We used the *F*-test to examine the significance of our regressions. We used one-way ANOVA followed by a Tukey's HSD post hoc test for comparisons of multiple mean values. If the criterion of homogeneity of variances was violated, we used the Games Howell test to compare multiple mean values. To conduct our GWAS, we used version 0.8.7. of the vcf2gwas platform. To determine significant genetic markers with a Bonferroni-corrected  $p < 0.05$ , we used a Wald test. We converted genotype files into vcf format, which is the only accepted format in vcf2gwas, using the TASSEL platform version 5.0 [80].

## 5. Conclusions

The findings of this study provide insights into the genetic and physiological principles of non-targeted-site resistance to diquat in *S. polyrhiza*. Since the analyzed genotypes showed gradual variation in their diquat resistance that could be associated with herbicide uptake kinetics and antioxidant responses, we suggest a polygenic mechanism behind the observed phenotypic variation in resistance levels. The association of gene candidates involved in apoptosis, pathogen response, starch metabolism and xenobiotic degradation points to a pleiotropic origin of diquat resistance from stress response pathways. Since most of the analyzed genotypes have likely never experienced selection through diquat, we suggest that the detected intra-specific variation in diquat resistance might originate from an adaption to environmental stress factors such as drought, UV stress, and herbivory.

Taken together our results contribute to a better understanding of the rapid evolution of novel resistance cases around the world. Association studies on the genetic basis of herbicide resistance are required to identify novel genetic signatures which can be used for the marker-associated breeding of herbicide resistance crop species or for the development of molecular screening methods for resistant weed species.

**Supplementary Materials:** The following supporting information can be downloaded at: <https://doi.org/10.5061/dryad.2fqz612ww>. Table S1: List of genotypes screened for their diquat resistance.

**Author Contributions:** Conceptualization, M.H. and S.X.; methodology, M.H., S.W., and M.S.; software, Y.W. and M.H.; validation, M.H.; formal analysis, M.H.; investigation, M.H. and S.W. and Y.W.; resources, S.X.; data curation, S.X.; writing—original draft preparation, M.H.; writing—review and editing, S.X.; visualization, M.H.; supervision, S.X.; project administration, S.X.; funding acquisition, S.X. All authors have read and agreed to the published version of the manuscript.

**Funding:** This research was funded by the German Research Foundation (DFG), grant number 427577435 to S.X. The LC-MS instrument was funded by the German Research Foundation (DFG), grant number 435681637 to S.X.

**Data Availability Statement:** Publicly available datasets including Supplementary Table S1 were analyzed in this study. These data can be found here: <https://doi.org/10.5061/dryad.2fqz612ww> (accessed on 3 February 2024).

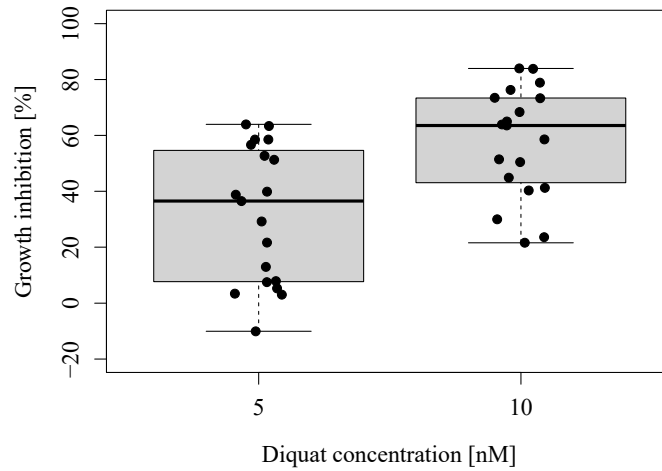

**Acknowledgments:** We thank Marie Sarazova for providing technical assistance and Alexander Kröger for his support in the toxicity assays.

**Conflicts of Interest:** The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as potential conflicts of interest.

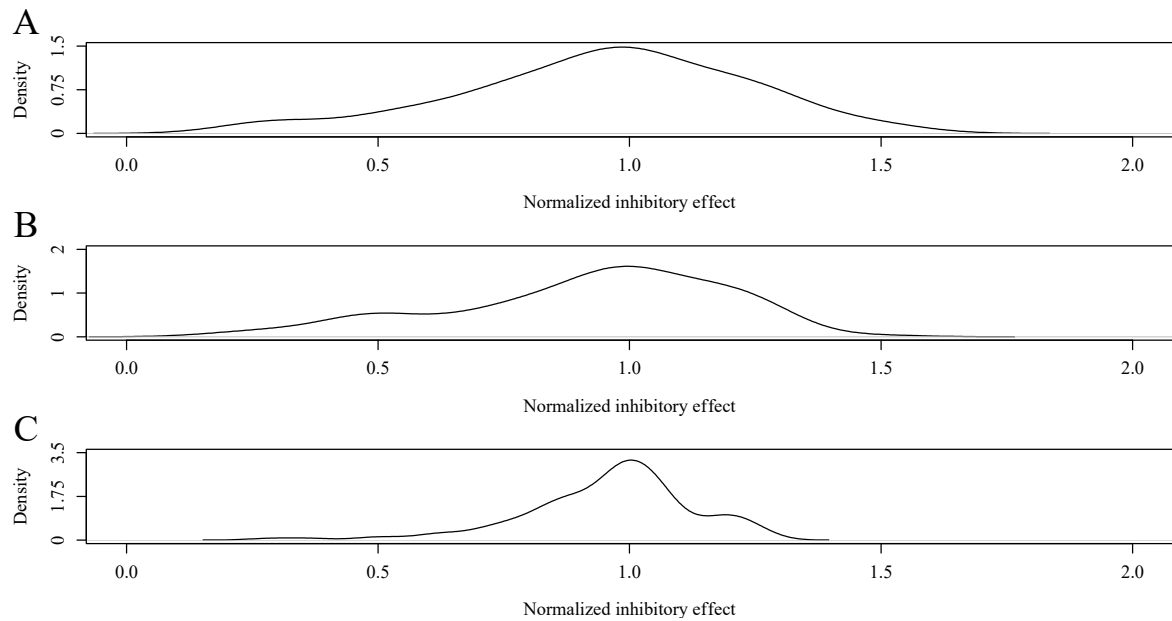

## Appendix A

**Figure A1.** Dose–response curve of two *S. polyrhiza* genotypes (SP077 and SP035) for various diquat concentrations. Mean IE values for FW (A) and RGR of frond number (B) are shown with their respective standard errors. The curves were fitted using the hormetic UCRS4c.

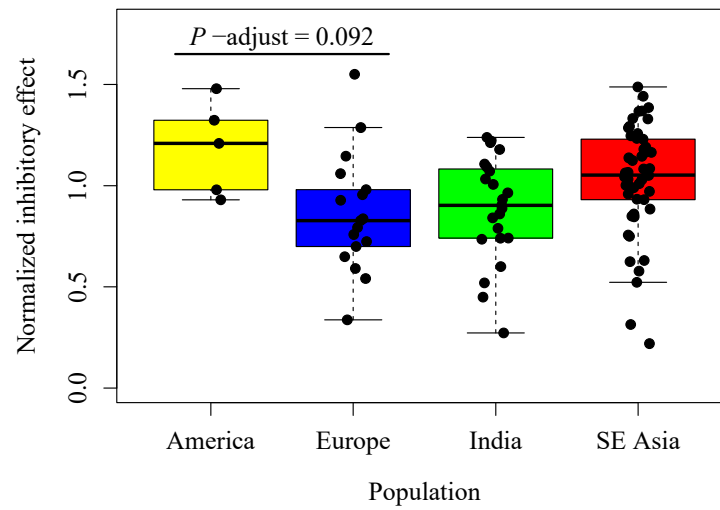

**Figure A2.** Distribution of IE of RGR of frond number values, here shown as growth inhibition in % from 19 genotypes cultivated at diquat concentrations of 5 nM and 10 nM. We observed hormetic effects for one genotype in the 5 nM treatment.

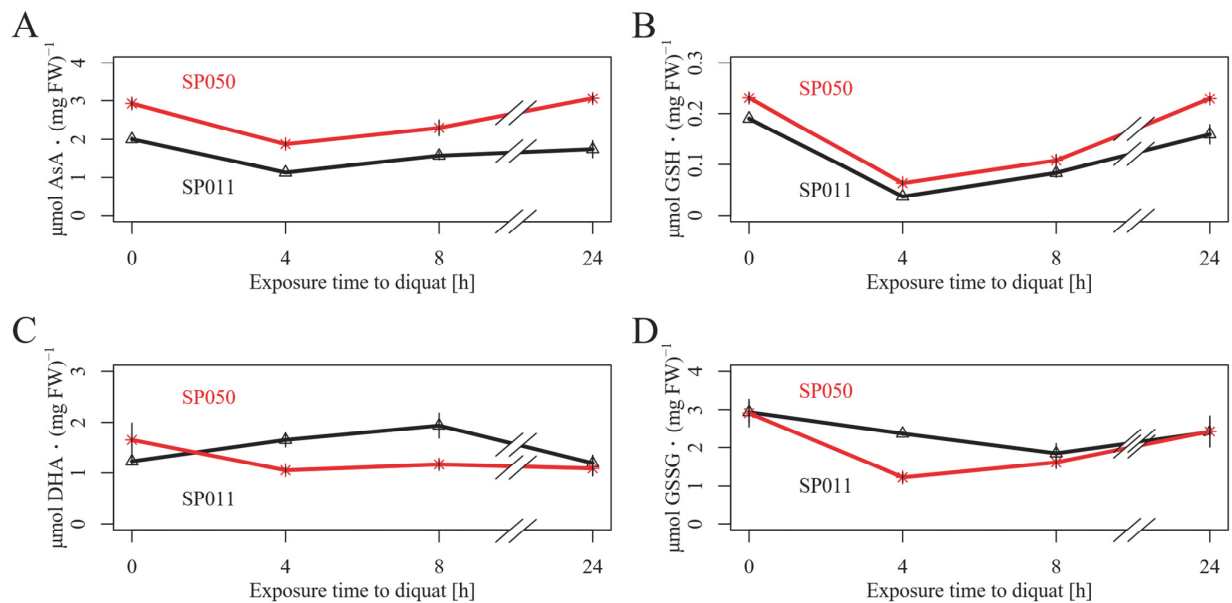

**Figure A3.** Density function of all diquat resistance cases shown by their normalized growth inhibition measured for the parameter's norm. IE of RGR frond number (A), norm. IE of RGR frond area (B), and the norm. IE of FW (C). The growth inhibition was normalized to the internal standard genotype SP028, whose diquat resistance was set at 1.0.

**Figure A4.** Correlation of inhibitory effect of diquat on several fitness parameters from the screening experiment with that of the dose-response curve experiment (drc) at a concentration of 10 nM: (A) RGR frond number, (B) RGR frond area, (C) FW.

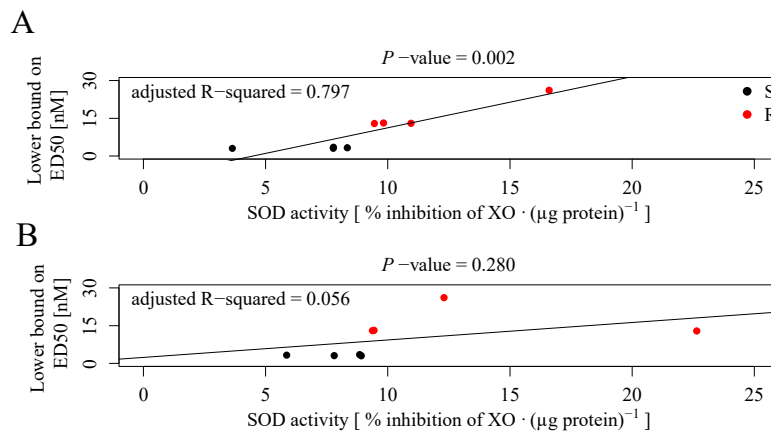

**Figure A5.** Population-wise distribution of resistance levels shown as normalized IE of RGR frond number for the 98 representative genotypes used in the GWAS.

**Figure A6.** Ascorbic acid (AsA), dehydroascorbic acid (DHA), reduced (GSH), and oxidized glutathione (GSSG) plant tissue concentrations in response to diquat are shown with their respective standard errors for SP050 and SP011. Whereas the reduction of AsA concentration was compensated by an increase in DHA, both GSH and GSSG decreased after 4 h of diquat exposure. (A) AsA concentration, (B) GSH concentration, (C) DHA concentration, (D) GSSG concentration. Mean values and standard errors were derived from four or five biological replicates.

**Figure A7.** The diquat plant tissue concentration after 24 h of diquat treatment was correlated to the corresponding GSH/GSSG (A) and AsA/DHA (B) molar ratios for the four R and four S genotypes (Table A2). Only the GSH/GSSG molar ratio was significantly associated with the diquat tissue concentration (F-test). In (C,D), the estimates of EC50 were correlated to the GSH/GSSG (C) and ASA/DHA ratios (D).

**Figure A8.** The resistance levels expressed as estimates of EC50 were correlated with the SOD activity measured under 24 h diquat treatment (A) or constitutive conditions (B). We used the four S and four R genotypes shown in Table A2 for this analysis. Diquat resistance correlated significantly with the SOD activity under diquat treatment (F-test). No such effect was found for the constitutive SOD activity.

**Figure A9.** Manhattan plots for a GWAS of diquat resistance calculated based on frond number (A) frond area (B) and freshweight (C). A synonymous SNP, causing a C-T transition in the coding sequence of *SpGBPL2*, is associated with an increased resistance measured by norm. IE of FW (Wald test). The Bonferroni corrected significance threshold (red line) was at  $p < 0.05$  is  $1.18 \times 10^{-6}$ . (D) Genotypes that are homozygous for the allele containing thymine instead of cytosine were significantly more resistant to diquat. \*\*\*—*p*-adjust < 0.001 (Games Howell test).

**Figure A10.** QQ plots for GWAS conducted on SNPs associated with diquat resistance traits. (A) norm. IE of RGR frond number (B) norm. IE of RGR frond area (C) norm. IE of FW.

**Figure A11.** QQ plots from GWAS conducted for structure variations on traits expressing diquat resistance. (A) norm. IE of RGR frond number (B) norm. IE of RGR frond area (C) norm. IE of FW.

**Figure A12.** (A) Exon–intron structure of *SpLOX2.1*. The 184 bp deletion is at the border between the fourth exon and fourth intron. (B) Genotypes that are heterozygous for the deletion were significantly more resistant than genotypes lacking the deletion. \*\*— $0.01 \geq p\text{-adjust} > 0.001$  (unpaired two-sided Student's *t*-test). Since only one genotype was homozygous for the deletion, we did not include this sample in our statistical analysis.

**Figure A13.** Genotyping of the deletion in *SpETHE1* and analysis of the gene splicing pattern in the *S. polyrhiza* genotypes SP050 and SP011. **(A)** Genomic DNA extracted from SP050 and SP011 was genotyped for the presence of the deletion in *SpETHE1*. The absence of the 94-bp deletion (WT/WT) results in a product of 799 bp length. As indicated by the shift of the amplicon band obtained for SP050, this genotype was homozygous for the deletion in *SpETHE1*. **(B)** A 330-bp fragment was amplified from cDNA pools with primers binding on exons flanking the intron with the 94 bp deletion for SP050 and SP011. The cDNA was synthesized with random hexameric primers to account for unstable RNA species. No products that deviated from the predicted 330-bp fragment were amplified from both genotypes. This indicates no differences in the splicing pattern of *SpETHE1* between the two genotypes.

**Figure A14.** Cont.

**Figure A14.** Relative expression of candidate genes in the roots. (A) *SpETHE1* time course expression under control conditions or after 4 and 72 h of diquat exposure. No significant differences in *SpETHE1* expression were found between SP011 and SP050. (B) *SpETHE1* root–frond expression ratio in SP050 and SP011 under control conditions and after diquat treatment for 4 and 72 h. *SpETHE1* expression was stronger in the root than in frond tissue by factors two to four in both genotypes. Expression differences in *SpDLH* (C), *SpTRB1* (D), *SpALA2* (E), and *SpSBE3* (F) between SP050 and SP011 are shown under control conditions. We detected a significantly reduced expression of *SpDLH* in SP050 compared to SP011.

## Appendix B

**Table A1.** Estimates of EC10 and EC90 values for the two *S. polyrhiza* genotypes SP035 and SP077. We derived the EC values for the inhibition of the fitness parameters biomass (FW) and growth rate (RGR of frond number) from a hormetic model (USCR4c).

Genotype	Biomass		Growth Rate	
	EC90 [nM] ± Standard Error [nM]	EC10 [nM] ± Standard Error [nM]	EC90 [nM] ± Standard Error [nM]	EC10 [nM] ± Standard Error [nM]
SP035	11.45 ± 1.65	1.76 ± 0.27	59.22 ± 31.7	2.20 ± 0.17
SP077	10.71 ± 8.10	1.85 ± 0.82	46.80 ± 20.6	2.25 ± 0.15

**Table A2.** The estimated EC50 values with their respective standard error are shown for 16 genotypes. According to this, we identified the four most resistant (R) and four most susceptible genotypes (S) for future experiments. The most resistant and most susceptible genotypes were SP050 and SP011, respectively.

Genotype	Four-Digit Code	Origin of Genotype	Estimated EC50 RGR Frond Number [nM] ± Standard Error [nM]	Fold Change to the Most Susceptible Genotype	Classification
SP007	7674	Nepal, Kathmandu	3.31 ± 0.47	1.08	S
SP011	9242	Ecuador, Guayas Yaguachi Nuevo	3.06 ± 0.52	1.00	S
SP031	9514	Austria, Vienna	4.47 ± 0.53	1.46	-
SP050	0090	China, Sichuan	26.13 ± 2.61	8.54	R

SP239	5613	Israel	7.87 ± 0.78	2.57	-

**Table A3.** Diquat medium concentration measured daily within one week (d0–d7) in cultures of SP011 and SP050. The starting point of the cultivation is termed as d0.

Timepoint	Diquat Medium Concentration [pmol/mL] ± Standard Error [pmol/mL]		
	Ctrl	SP011	SP050
d0	8.11 ± 0.18	8.23 ± 0.13	8.58 ± 0.02
d1	8.47 ± 0.32	8.62 ± 0.18	8.55 ± 0.08
d2	7.86 ± 0.14	8.65 ± 0.18	8.60 ± 0.10
d3	8.04 ± 0.10	8.50 ± 0.06	9.00 ± 0.13
d4	8.67 ± 0.36	9.13 ± 0.03	8.73 ± 0.34
d5	8.73 ± 0.18	9.02 ± 0.17	9.38 ± 0.12
d6	9.00 ± 0.22	8.81 ± 0.46	9.12 ± 0.40
d7	8.84 ± 0.08	8.48 ± 0.54	9.60 ± 0.41

**Table A4.** Significant SNPs associated with diquat resistance in *S. polyrhiza*.

Marker	Parameter(s)	Chromosome	Location	<i>p</i> -Wald	Comment
<i>SpGBPL2</i> -MUT	norm. IE of FW	1	10117635	$2.55 \times 10^{-9}$	Location in the coding sequence of Guanylate binding protein-like 2 ( <i>SpGBPL2</i> )

**Table A5.** Significant SVs associated with diquat resistance in *S. polyrhiza*.

Marker	Parameter(s)	Size	Chromosome	Location	<i>p</i> -Wald	Comment
<i>SpETHE1</i> -DEL	norm. IE of RGR frond number, norm. IE of RGR area, norm. IE of FW	94 bp	8	5199142	$5.49 \times 10^{-8}$ (norm. IE of RGR frond number), $1.23 \times 10^{-6}$ (norm. IE of RGR frond area), $8.89 \times 10^{-6}$ (norm. IE of FW)	Deletion located in the intronic region of <i>SpETHE1</i> : mitochondrial ETHE1 persulfide dioxygenase
Intergenic region	norm. IE of FW	56 bp	5	5617685	$1.14 \times 10^{-6}$	Insertion intergenic region
<i>SpLOX2.1</i> -DEL	norm. IE of RGR area	184 bp	5	7048033	$3.45 \times 10^{-5}$	Deletion located in <i>SpLOX2.1</i> : chloroplastic lipoxygenase 2.1

**Table A6.** Primers used for genotyping *S. polyrhiza* genotypes to check the presence or absence of the intronic deletion in *SpETHE1*.

Name	Sequence Primer 5'-3'
1_ETHE1_fwd	GGTGGAGGAGGAGAGCAAGTACAAC
2_ETHE1_rev	GCACGGCCACGTCGATCATCTTC
3_ETHE1_fwd	GCTGCGTAACGTATGTACAGGCG

**Table A7.** Primers used for RT-qPCR studies. The sequences of the primer pairs for *SpaEF* and *SpGAPDH* were published previously [37].

Fwd Primer 5'-3'	Rev Primer 5'-3'	Gene	Gene ID	Product Size	Efficiency
TCGAAGCCGGCATTTC AAGGACG	TCGCCTTCGAGTACTTGGG	<i>SpaEF</i>	SpGA2022_005771	129 bp	99.8%

## 3.2 Genome-Wide Association Study of Metabolic Traits in the Duckweed *Spirodela polyrhiza*

### 3.2.1 Summary

In this study we aimed to elucidate the genetic basis of free metabolite levels and growth in *Spirodela polyrhiza*.

For this, we characterized the profiles of 42 metabolites and growth in 137 *S. polyrhiza* genotypes and identified SNPs and structure variations associated with these traits using a GWA approach. Growth was quantified as fresh weight, dry weight, relative growth rate (RGR) of frond area and RGR of frond number. Metabolites, including 20 amino acids and related compounds, 11 specialized metabolites and 11 phytohormones were quantified by LC-MS.

Among all quantified metabolites L-Asparagine and L-Glutamine were found to be most abundant in *S. polyrhiza*. On average, specialized metabolites showed higher amounts of intraspecific variation than amino acids and phytohormones. Whereas correlations of most amino acids with biomass were positive, specialized metabolites were mostly negatively associated with biomass. Among all metabolites, Cyanidine-3-O-glycoside showed the strongest negative correlation patterns with growth, either measured by increase of frond number or area.

We applied a GWA approach to identify the genetic background controlling growth and metabolite levels. Although no SNPs were associated with growth traits, we identified many genetic markers jointly associated with the contents of several metabolites. Among them, we identified markers linked to the *LIGHT-HARVESTING-CHLOROPHYLL-A/B-BINDING PROTEIN 5* (*SpLHCB5*), the *UBIQUITIN-CARBOXYTERMINAL HYDROLASE 7* (*SpUBP7*), the *U-BOX CONTAINING PROTEIN 4* (*SpPUB4*) and the transcription factor *SpMYBC1* to be associated with metabolites, positively correlated to plant biomass. Marker presence was associated with an increased expression level of *SpUBP7* in root tissue, studied by qPCR.

Together, this study revealed strong positive correlation patterns between contents of various amino acids and biomass. Further, multiple genes controlling photosynthesis (*SpLHCB5*), protein-degradation (*SpUBP7*), cell-cycle (*SpPUB4*) and secondary metabolite synthesis (*SpMYBC1*) were associated with biomass-associated traits. The identified candidate genes are therefore of potential use for the simultaneous optimization of biomass and metabolite contents in duckweed.

### 3.2.2 Zusammenfassung

Das Ziel dieser Studie lag in der Ergründung der genetischen Basis metabolischer Eigenschaften und des Wachstums von *Spirodela polyrhiza*.

Hierfür wurde die Wachstumsgeschwindigkeit und die Konzentrationen von 42 Metaboliten in 137 Genotypen von *S. polyrhiza* bestimmt. Anschließend wurden mit diesen Eigenschaften assoziierte SNPs und strukturelle Variationen ermittelt. Wachstum wurde in Form der relativen Wachstumsrate gemessen an Frondanzahl und -fläche, sowie anhand der Biomasse als Frisch- oder Trockengewicht bestimmt. Die Metaboliten, bestehend aus 20 Aminosäuren und strukturell eng verwandten Verbindungen, 11 Sekundärmetaboliten und 11 Phytohormonen wurden mittels LC-MS quantifiziert.

Innerhalb aller quantifizierten Metaboliten zeigten L-Asparagin und L-Glutamin die höchsten Konzentrationen im Pflanzengewebe. Im Durchschnitt zeigten Konzentrationen von Sekundärmetaboliten ein höheres Maß an intraspezifischer Variabilität verglichen mit Aminosäuren und Phytohormonen. Während Aminosäurelevel vorwiegend positiv mit der pflanzlichen Biomasse korrelierten, waren Sekundärmetabolitlevel vorwiegend negativ mit der Biomasse korreliert. Innerhalb aller quantifizierter Metabolite zeigte Cyanidin-3-O-glykosid die stärksten negativen Korrelationen zu den gemessenen Wachstumsraten. Zur Identifikation der genetischen Basis des pflanzlichen Wachstums und der Metabolitkonzentrationen wurde eine Genomweite Assoziationsstudie durchgeführt. Insgesamt konnten keine SNPs mit Wachstumsparametern assoziiert werden. Allerdings sind zahlreiche Marker, die mit mehreren Metabolitkonzentrationen simultan assoziiert sind, gefunden worden. Beispielsweise sind Marker innerhalb oder in starker Nähe zu dem *LIGHT-HARVESTING-CHLOROPHYLL-A/B-BINDING PROTEIN 5* (*SpLHCB5*), dem *UBIQUITIN-CARBOXYTERMINAL HYDROLASE 7* (*SpUBP7*), dem *U-BOX CONTAINING PROTEIN 4* (*SpPUB4*) oder dem Transkriptionsfaktor *SpMYBC1* mit gleichzeitig mit mehreren Metaboliten assoziiert, die positiv mit pflanzlicher Biomasse korrelieren. Die innerhalb von *SpUBP7* gefundene Strukturvariation war mit einer erhöhten Expression des Gens assoziiert.

Insgesamt identifizierte die Studie starke positive Korrelationen zwischen verschiedensten Aminosäuren und pflanzlicher Biomasse. Weiterhin wurden Gene, welche funktional in Prozessen wie Photosynthese (*SpLHCB5*), Proteinabbau (*SpUBP7*), Zell-Zyklus Kontrolle (*SpPUB7*) und Sekundärmetabolitbiosynthese (*SpMYBC1*) involviert sind mit Metaboliten assoziiert, die positiv mit Biomasse korrelieren. Aufgrund dessen, können die identifizierten Kandidatengene zur simultanen Optimierung von Biomasse und Metabolitleveln dienen.

### 3.2.3 Statement of Contribution

This project was planned and coordinated by Shuqing Xu and Martin Höfer. Growth rates of the 137 genotypes were recorded by Yangzi Wang, Samuel Wink and Martin Höfer. Martin Schäfer and Samuel Wink conducted all metabolite extractions and LC-MS based quantifications. Martin Höfer analyzed all data, created all figures and wrote the first draft of this manuscript. All co-authors provided feedback on the manuscript.

11           **Abstract**

12           The exceptionally high growth rate and high contents of flavonoids make the giant  
13 duckweed *Spirodela polyrhiza* (L.) Schleid. (Arales: Lemnaceae) an ideal organism for  
14 food production and metabolic engineering. To facilitate this, identification of the  
15 genetic basis underlying growth and metabolic traits is essential. Here, we  
16 characterized the genetics underpinning the growth and contents of 42 metabolites in  
17 *S. polyrhiza* using a genome-wide association (GWA) approach. We found that  
18 biomass positively correlates with contents of many free amino acids, including L-  
19 Glutamine, L-Tryptophane and L-Serine, but negatively correlates with many  
20 specialized metabolites, such as flavonoids. GWA analysis showed that several  
21 candidate genes were simultaneously associated with several metabolic traits,  
22 qualifying them as targets for growth manipulation and metabolic engineering.  
23 Together, this study provides insights into the metabolic diversity of *S. polyrhiza* and  
24 its underlying genetic architecture, paving the way for industrial applications of this  
25 plant via targeted breeding or genetic engineering.

28 duckweed metabolism

29

## 30 **Introduction**

31 With a biomass duplication rate of less than two days, *S. polyrhiza* is one of the world's  
32 fastest-growing angiosperms (Ziegler et al. 2015). Due to its high levels of flavonoids  
33 and amino acids, *S. polyrhiza* is one of the best organisms for producing food  
34 resources and pharmaceuticals (Acosta et al. 2021; Baek et al. 2021; Zhao et al. 2015;  
35 Smith et al. 2024). To fully realise its industrial potential, specific improvements on its  
36 growth and metabolite production are needed, which requires a detailed understanding  
37 of the genetic mechanisms controlling these traits. Although previous forward genetic  
38 studies on metabolic traits in species like *Zea mays* L. (Poales: Poaceae) (Chen et al.  
39 2016), *Oryza sativa* L. (Poales: Poaceae) (Chen et al. 2014; Zhang et al. 2019; Cu et  
40 al. 2021) and *Arabidopsis thaliana* (L.) Heynh. (Brassicales: Brassicaceae) (Angelovici  
41 et al. 2013; Angelovici et al. 2017) identified many promising candidate genes, the  
42 genetic principles controlling growth and plant metabolisms in *S. polyrhiza* largely  
43 remain unknown, hampering its further biotechnological optimization.

44 For most plants, to survive from natural stress factors, such as herbivory, they  
45 must carefully allocate their resources to growth or defense pathways. On a molecular  
46 level, free amino acids play a pivotal role in balancing resource distribution between  
47 biomass production and the synthesis of defense metabolites. Biosynthesis of amino  
48 acids can account for 50% of all carbon compound syntheses and consume 32% of  
49 total fixed carbon dioxide (Smith et al. 1961), making them a major carbon sink for  
50 biomass production in plants (Noctor and Foyer 1998). The central metabolic function  
51 of free amino acids is highlighted by their association with key metabolic pathways  
52 such as glycolysis, tri-carboxylic-acid (TCA) cycle, pentose-phosphate-pathway, urea-

53 cycle and photorespiration (Figure 1) (Noctor and Foyer 1998). Besides their function  
54 in biomass gain, amino acids are precursors of many specialized metabolites like  
55 flavonoids and phenolic acids (Figure 1), which are involved in plant defense. Yet, the  
56 biosynthesis of specialized metabolites often negatively impacts plant biomass,  
57 primarily through the consumption of large nutrient resources (Züst et al. 2011) and  
58 autotoxicity (Dick et al. 2012; Li et al. 2021). Consequently, optimization for high crop  
59 yields often leads to high susceptibilities to pests due to a lack of defense metabolites,  
60 a phenomenon known as growth-defense trade-off (Züst and Agrawal 2017; Huot et  
61 al. 2014). On a regulatory level resource allocation from growth to defense pathways  
62 is controlled by phytohormones such as Jasmonic acid (JA), Abscisic acid (ABA),  
63 Salicylic acid (SA) and Auxin (IAA) (Huot et al. 2014; Hui et al. 2023; Aftab et al. 2010;  
64 Živanović et al. 2020a). Therefore, understanding the genetic mechanism controlling  
65 levels of phytohormones, free amino acids and related metabolites represents the key  
66 for optimizing the biomass yield and specialized metabolite contents in plants.

67 Here, we focus on understanding the genetic control regulating levels of free amino  
68 acids and their related specialized metabolites in the giant duckweed. We quantified  
69 the contents of 42 metabolites (Figure 1) in 137 genotypes of *S. polyrhiza* and  
70 performed a genome-wide association study on the contents of these metabolites. We  
71 aim to address the following questions: 1) To what extent do growth and metabolism  
72 vary in *S. polyrhiza*? 2) which metabolites are associated with biomass and growth?  
73 and 3) which genes control these metabolic traits?

74

## 75 **Materials and Methods**

### 76 **Data collection and sample preparation**

77 In a previous study we estimated the growth of 138 *S. polyrhiza* genotypes under  
78 herbicide treatment and under control conditions (Höfer et al. 2024b). We quantified

79 growth as relative growth rates (RGR) of frond area and frond number and as fresh  
80 weight and dry weight at the end of a seven-day growth period. For each genotype  
81 growth was estimated from three technical replicates. The quantified growth  
82 parameters are publicly available (Höfer et al. 2024a). A table documenting the  
83 geographic origins of all genotypes analyzed in this study can be found at:  
84 [https://datadryad.org/stash/downloads/file\\_stream/2894056](https://datadryad.org/stash/downloads/file_stream/2894056).

85 All analyses included in this study were based on plant material grown under control  
86 conditions (Höfer et al. 2024b). After harvesting, we freeze-dried plant material and  
87 stored it at room temperature (RT) till metabolite extraction. To have sufficient plant  
88 material for metabolite analysis, triplicates were pooled for each genotype. The RGRs  
89 were estimated (Höfer et al. 2024b) based on a published method (Ziegler et al. 2015),  
90 applying the formula:  $RGR = \frac{\ln(N_t) - \ln(N_0)}{t}$ , where  $N_t$  is the frond number / area at the  
91 endpoint of the assay,  $N_0$  is the frond number at the start of the cultivation and  $t$  as the  
92 duration of the bioassay.

93

#### 94 **Metabolite extraction**

95 To investigate genotypic variation in metabolite contents via LC-MS, we extracted 42  
96 metabolites from pooled triplicates of 137 genotypes (Table S1, Figure 1). The number  
97 of analyzed genotypes was reduced from 138 to 137 due to mislabelling of one  
98 genotype, which was excluded from all analyses. The protocols used for LC-MS  
99 analysis of metabolite levels from different fractions are listed as Methods S1-5 in the  
100 supplemental part. The entire extraction procedure and quantification procedure is  
101 based on a method published previously (Schäfer et al. 2016).

102 The samples were ground with two steel balls at 30 Hz for 30 s in a TissueLyser  
103 (Qiagen, Venlo, Netherlands). Next, we aliquoted 10 mg of the homogenized samples  
104 in 96-well BioTubes (Axygen, New York, NY, USA). We then applied 800  $\mu$ L of

105 extraction buffer (methanol:water:formic acid (15:4:1) (v/v)) mixture containing [<sup>13</sup>C<sub>6</sub>]-  
106 IAA (1 ng), [<sup>2</sup>H<sub>5</sub>]-JA (10 ng), [<sup>2</sup>H<sub>6</sub>]-ABA (10 ng), [<sup>2</sup>H<sub>4</sub>]-SA (10 ng), [<sup>2</sup>H<sub>5</sub>]-tZ (0.5 ng), [<sup>2</sup>H<sub>6</sub>]-  
107 iP (0.2 ng) and [<sup>2</sup>H<sub>6</sub>]-iPR (0.2 ng) to each tube. We sealed the plate with a pre-cooled  
108 mat and homogenized the samples in a TissueLyser at 25 Hz for 60 s. Samples were  
109 incubated at -20 °C overnight. After that, we repeated the homogenization step at 25  
110 Hz for 60 s. We then centrifuged the samples at 2250 g for 20 min at 4 °C and  
111 transferred 600 µL of the supernatant in new BioTubes, that were pre-cooled to -20 °C  
112 previously. The pellet was kept for re-extraction. We diluted an aliquot of 1 µL of the  
113 supernatant in 99 µL of algae amino acid standard mix -<sup>13</sup>C, <sup>15</sup>N (0.5 ng/µL) (Sigma-  
114 Aldrich, St. Louis, MO, USA) and transferred the dilutions in 96-well PCR plates  
115 (Kisker, Steinfurt, Germany). The PCR plates were then stored at -20 °C till analysis  
116 of all amino acids and several secondary metabolites (Methods S1 and S2, Table S1).  
117 The pellet was reextracted with 600 µL of extraction buffer without standards. We  
118 homogenized the reextracted samples at 25 Hz for 60 s before incubation at -20 °C for  
119 30 min. After another centrifugation step at 2250 g for 20 min at 4 °C, we mixed 600  
120 µL of the supernatant from the reextracted samples with the remaining supernatant  
121 from the first part of the extraction. We centrifuged the combined supernatants at 2250  
122 g for 20 min at 4 °C. Before loading our samples, we conditioned the HR-X columns  
123 (Macherey-Nagel, Düren, Germany) with 600 µL of MeOH, followed by 600 µL of  
124 extraction buffer and discarded the flow through. We collected the flow-through of our  
125 samples in Nunc 96-well Deep Well Plates (Thermo Fisher Scientific, Waltham,  
126 Massachusetts, USA). Next, we applied another 200 µL of extraction buffer and  
127 collected the flow through in the same well plate. We then evaporated the MeOH at 45  
128 °C. Next, we added 850 µL of 1 N formic acid to each sample, mixed the samples at  
129 20 Hz for 30 s using a TissueLyser and centrifuged them at 2250 g for 20 min at 4 °C.  
130 Before starting the next purification step, we conditioned HR-XC columns with 600 µL

131 MeOH and afterwards with 600  $\mu$ L 1 N formic acid. The flow-through was discarded.  
132 We loaded the samples on the conditioned HR-XC columns and subsequently washed  
133 the columns with 1.2 mL of 1 N formic acid. We discarded the flow through and eluted  
134 the sample with 1 mL of 0.2 N formic acid in 80% (v/v) MeOH. We collected the eluates  
135 in BioTubes. After sample homogenization by inversion, we transferred 50  $\mu$ L of the  
136 supernatant into a 96-well PCR plate for analysis of phytohormones (Method S3, Table  
137 S1). The sealed plates were stored at -20 °C till analysis.

138 For analysis of Indole-3-acetic acid (IAA) and phenolic acids (Method S4), the  
139 remaining eluate was evaporated under a constant nitrogen stream at 45 °C and  
140 samples were reconstituted to 50  $\mu$ L with 0.2 N HCOOH in 80% (v/v) MeOH. We  
141 covered the plates before mixing at 20 Hz for 30 s. After centrifugation, samples were  
142 transferred to a 96-well PCR plate and were stored till analysis at -20 °C. For extraction  
143 of cytokinins (Method S5), we washed the HR-X column twice with 1 mL of 0.35 N  
144 NH<sub>4</sub>OH. Cytokinins were finally eluted with 1 mL of 0.35 N NH<sub>4</sub>OH in 60% (v/v)  
145 methanol. The samples were then dried under constant nitrogen flow. Next, we  
146 reconstituted sample volume to 50  $\mu$ L with 0.1% (v/v) acetic acid. The samples were  
147 then homogenized at 20 Hz for 30 s, before incubation in the ultrasonic bath for 5 min.  
148 The samples were centrifuged at 2250 g for 20 min at 4 °C, and the supernatant was  
149 transferred to a 96-well PCR plate and stored at -20 °C until analysis (Method S5).

150

### 151 **LC-MS analysis of metabolite contents**

152 We quantified all metabolites via LC-MS. For separation and quantification, we used a  
153 Nexera X3 UHPLC system (Shimadzu, Kyoto, Japan) coupled to an LCMS-8060  
154 system (Shimadzu). For separation of all metabolites, we used a Zorbax RRHD Eclipse  
155 XDB-C<sub>18</sub> column (50 x 3 mm, 1.8  $\mu$ m) (Agilent, Santa Clara, CA, USA) with a 1290  
156 Infinity II inline filter (0.3  $\mu$ m) (Agilent). For all measurements, the autosampler was

157 pre-cooled to 5 °C during the entire measurement procedure. As a mobile phase, we  
158 used a mixture of 0.05% (v/v) of formic acid and 0.1% (v/v) acetonitrile as solvent A  
159 and 100% methanol as solvent B, that were applied in gradient mode at a constant  
160 flow rate of 0.5 mL/min in all methods. The column oven temperature was always 42  
161 °C. For analyses, we used an electrospray ionization source with the following  
162 parameters: nebulizing gas flow: 3 L/min, heating gas flow: 10 L/min, drying gas flow:  
163 10 L/min, interface temperature: 300 °C, DL temperature: 250 °C, heat block  
164 temperature: 400 °C and CID gas flow: 270 kPa. For metabolites measured in the  
165 positive and negative ionization modes, we applied interface voltages of 4000 V and -  
166 3000 V, respectively (Table S2-6). A detailed description of individual metabolite  
167 analysis can be found in the supplemental (Method S1-5).

168

### 169 **Correlation and Principal Component Analysis**

170 Next, we used regression and principal component analysis (PCA) to identify  
171 correlation patterns between metabolic parameters and to identify the influences of  
172 population structure on metabolite levels and growth. We established multiple  
173 correlations for all metabolite and growth data using the ggcorrplot R-package (version  
174 0.1.4.1) (Kassambara 2023). We used the Pearson correlation coefficient to measure  
175 the strength of our linear correlations. All PCAs were conducted using the R package  
176 pcaMethods (version 1.88.0) (Stacklies et al. 2007). We calculated 95% confidence  
177 intervals based on standard deviations using the vegan package (version 2.6-2)  
178 (Oksanen et al. 2022) for all PCAs. All three-dimensional scatter plots were created  
179 using the R package scatterplot3d (version 0.3.42) (Ligges et al. 2003). For identifying  
180 metabolite categories, which strongly cluster together, we sorted all 42 metabolites into  
181 nine groups based on their chemical characteristics and biochemical precursors:  
182 Flavonoids, Phenolic acids, Aromatic amino acids, Glutamate family, Jasmonates,

183 Serine family, Pyruvate family, Aspartate family and Cytokinins (Figure 1). The PCA  
184 on metabolite concentrations was subsequently done for all 137 genotypes.

185 Since *S. polyrhiza* has four genetic populations, as previously described by our  
186 lab (Wang et al. 2024; Xu et al. 2019), we next investigated to which extent differences  
187 in metabolite concentrations and growth are explained through population level.  
188 Assignment of the genotypes to different genetic populations was done in one of our  
189 previous studies (Wang et al. 2024). Due to the high proportion of clonal phenotypes  
190 in our accession, 137 genotypes were grouped into 97 clonal families for PCA on  
191 population structure of growth parameters and metabolite levels, respectively. For  
192 analysis, each clonal family was represented by the genotype with the highest  
193 sequencing coverage, as described previously (Höfer et al. 2024b).

194

## 195 **GWAS**

196 To explore the genetic background underlying metabolic traits, we conducted GWAS  
197 on growth data and metabolite contents of all representative genotypes. We used  
198 single nucleotide polymorphisms (SNPs) and structural variations (SVs) (> 50 bp) as  
199 genetic markers for all GWAS analyses. To allow their usage for GWAS, SVs were  
200 recoded according to a previously published method (Lemay and Malle 2022). To  
201 correct for missing data, we performed an imputation of both SNP and SV data sets  
202 using beagle 5.4 version 22Jul22.46e (Browning et al. 2018).

203 We conducted GWAS on SNP and SV data using the vcf2gwas platform  
204 (version 0.8.7) (Vogt et al. 2021). Markers were pruned using the Plink software  
205 integrated into vcf2gwas, with phased  $r^2$  thresholds of 0.33 and 0.15 for SVs and SNPs,  
206 respectively. For filtering low abundant alleles, we applied a minor allele frequency  
207 (MAF) threshold of 5%, giving 10,057 SNPs and 1182 SVs for analysis. We corrected  
208 for population structure through principal component analysis (PCA) from the input

209 genotype files. Here, we estimated population structure based on four PCs accounting  
210 for the four genetic populations of *S. polyrhiza*. All GWAS were conducted using a  
211 univariate linear mixed model (Zhou and Stephens 2012). The genotypic data,  
212 including the annotation, were published previously (Wang et al. 2024) and can be  
213 found under: [https://github.com/Xu-lab-Evolution/Great\\_duckweed\\_popg](https://github.com/Xu-lab-Evolution/Great_duckweed_popg) (accessed  
214 on 22 March 2024).

215

### 216 **RT-qPCR quantification of candidate genes**

217 Our GWAS detected a deletion in *SpUBP7* that was associated with increased  
218 contents of L-Glutamine and L-Serine. To validate the effect of the deletion on gene  
219 function, we studied the expression of *SpUBP7* (*SpGA2022\_056000*) in two different  
220 allelic backgrounds.

221 For this we cultivated genotypes SP012 (low contents of L-Serine and L-  
222 Glutamine, no deletion in *SpUBP7*) and SP187 (high contents of L-Serine and L-  
223 Glutamine, homozygous for deletion in *SpUBP7*) in N-medium (Appenroth 2015) at 26  
224 °C, 135  $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$  16 h/8 h light/dark rhythm. For each genotype, five  
225 replicates were made, each consisting of ten fronds growing as colonies. The fronds  
226 were cultivated in plastic beakers (Verpackungsbecher PP, transparent, round, 250  
227 mL, Plastikbecher.de GmbH, Giengen, Germany), which were covered with perforated  
228 lids to allow gas exchange. Each beaker was filled with 150 mL N-medium.

229 After five days of cultivation, we harvested the root and frond tissue of each  
230 replicate separately for RNA extraction. We extracted RNA from < 20 mg fresh weight  
231 using the InnuPREP RNA mini kit (Analytik Jena, Jena, Germany). For each sample,  
232 RNA concentration was measured using a Nanodrop and integrity was checked via  
233 gel-electrophoresis on a 1% agarose gel. We used 600 ng of RNA for each cDNA  
234 synthesis following the instructions of the RevertAid First Strand cDNA synthesis kit

235 (Takara, Shiga, Japan). For all cDNA syntheses, we used Oligo-dT primers. qPCRs  
236 were carried out using a RotorGene Q system (Qiagen, Venlo, The Netherlands)  
237 applying a time program with an initial denaturation of 98 °C – 3 min, followed by 40  
238 cycles with 98 °C for 3 s and 60 °C for 20 s. Before qPCR, we estimated primer  
239 efficiency for *SpUBP7* by using serial dilutions of pooled cDNA templates from root  
240 and frond tissue samples. Primer specificity was checked by evaluating qPCR products  
241 on a 2% agarose gel and by melting curve analysis. We conducted all qPCR reactions  
242 according to the instructions of the KAPPA SYBR FAST kit (Roche, Basel,  
243 Switzerland). All cDNA samples were diluted in a 1:100 ratio in nuclease-free water  
244 before analysis. We used the alpha-elongation factor one gene *SpaEF*  
245 (*SpGA2022\_005771*) and the glycerinaldehyd-3-phosphate dehydrogenase gene  
246 *SpGAPDH* (*SpGA2022\_054082*) as references for visualization of candidate gene  
247 expression according to the delta-delta Ct method with multiple reference genes as  
248 published previously (Hellemans et al. 2007). The primers used for this qPCR study  
249 can be found in Table S7. The primers for the reference genes *SpaEF* and *SpGAPDH*  
250 were used in previous publications (Höfer et al. 2024b; Wang et al. 2024).

251

## 252 **Software and Statistics**

253 We conducted all statistical analyses with R version 4.2.0. Standard errors of means  
254 were calculated using the plotrix R package (Lemon 2006). For all LC-MS  
255 measurements, we recorded and quantified analyte and standard peaks with  
256 LabSolutions software version 5.97. We estimated the broad sense heritability (H<sup>2</sup>.c)  
257 from our comprehensive data set, which includes repeatedly analyzed genotypes with  
258 the lme4 R package (Bates et al. 2015) following a method previously published by  
259 Cullis et al. (2006).

260 The significance of correlations was evaluated using the F-test. We used  
261 Bonferroni corrected  $P$ -value  $< 0.05$  to determine significant genetic markers  
262 associated with our traits. The  $P$ -values for GWAS were calculated using the Wald test.  
263 In case of *SpUBP7*, we compared the SV effect of heterozygous and WT samples  
264 using a two-sided Student's  $t$ -test. We used Student's  $t$ -test for comparison of gene  
265 expression between two genotypes. We conducted the Levene test to check for  
266 homogeneity of variances using the car R package (Fox and Weisberg 2019).

267

## 268 **Results**

### 269 **Intraspecific variation of growth rate and metabolic traits**

270 We quantified 42 metabolites, including 20 free amino acids and their derivatives, 11  
271 secondary metabolites and 11 phytohormones (Figure 1) among 137 *S. polyrhiza*  
272 genotypes. We found L-Asparagine and L-Glutamine were the most abundant free  
273 amino acid in *S. polyrhiza*, having average genotype tissue concentrations of 114.4  
274  $\mu\text{mol}/\text{mg DW}$  and 57.0  $\mu\text{mol}/\text{mg DW}$ , respectively (Table S8). Abscisic acid (ABA) was  
275 the least abundant metabolite, showing an average concentration of 37  $\text{pmol}/\text{mg DW}$   
276 (Table S9).

277 Among all quantified metabolic features contents of flavonoids and phenolic  
278 acids showed the highest amounts of intraspecific variation (Table S10, Figure S1-4).  
279 Chlorogenic acid and Luteolin-7-O-glycoside showed 214.9 and 183.8-fold differences,  
280 respectively, among genotypes (Table S10, Figure S3). Growth rate, either quantified  
281 as RGRs of frond number or frond area, had less than 2.4-fold differences (Figure S1).

282 On average, growth parameters also appeared to have a higher broad-sense  
283 heritability than metabolites (Table 1, Table S8-10). All growth parameters showed  
284 overall high broad-sense heritability values between 0.6 and 0.9, with fresh weight  
285 being the most heritable (Table 1). We found 25 metabolites reached high heritability

286 values ( $H^2.c > 0.3$ ). The remaining 16 metabolites showed low heritability ( $H^2.c < 0.3$ )  
287 (Table S8-10). Together, these findings suggest that growth rate and metabolic traits  
288 are variable within *S. polyrhiza*, and the majority of these traits are heritable.

289

### 290 **Metabolic traits correlate with biomass and growth**

291 Plant metabolic traits are often associated with growth and biomass (Angelovici et al.  
292 2013; Chen et al. 2016; Živanović et al. 2020b; Cu et al. 2021). In *S. polyrhiza*, we  
293 found plant metabolites showed higher correlations with biomass than with growth rate.  
294 In total, we found 19% and 29% of quantified metabolites showed significant  
295 correlation with growth rate (RGR of frond number and frond area) and biomass (fresh  
296 weight and dry weight) (Figure 2A, Figure S5 and S6), respectively. Among 20  
297 quantified free amino acids, 11 showed a significant positive correlation with biomass  
298 (dry weight), including L-Glutamine, L-Tyrosine, L-Serine and L-Threonine (Figure 2A,  
299 Figure S6), whereas five were positively correlated with growth rate (RGR of frond  
300 number). Among phytohormones, only IAA and JA-Ile showed a positive correlation  
301 with biomass. Interestingly, most of the quantified specialized metabolites, while  
302 positively correlated with cytokinins, were negatively correlated with biomass (Figure  
303 2A). Among all metabolites, Cyanidine-3-C-glycoside showed the strongest negative  
304 correlation with both growth rate and biomass (fresh weight) (Figure 2A, Figure S5 and  
305 S7).

306       Among the quantified metabolites, we found strong correlations within each  
307 metabolite group (Figure S8). Most of the free amino acids are positively correlated  
308 with each other and with flavonoids. Phenolic acids often were positively correlated  
309 with flavonoids (Figure 2A), reflecting their biosynthetic relationships (Figure 1).

310       Because *S. polyrhiza* has a strong population structure (Wang et al. 2024; Xu  
311 et al. 2019), which can confound the phenotypic variations and reduce the power of

312 GWAS. We further investigated whether metabolisms differed among populations,  
313 using a principal component analysis (PCA). The results showed that there are no  
314 population-specific differences at the metabolic level (Figure 2B), indicating GWAS can  
315 be used for most of the metabolic traits in *S. polyrhiza*.

316

### 317 **GWAS of metabolite traits**

318 We used a GWA approach to identify the genetic basis underlying different metabolic  
319 traits. Here, we focused on 10057 unlinked SNPs and 1182 SVs. A total of 75 SNPs  
320 and 15 SVs were significantly associated with the 42 metabolites (Table S11-13).  
321 Among them, 13 SNPs and three SVs were found to be associated with several  
322 metabolites, indicating their pleiotropic role in metabolisms. Surprisingly, we did not  
323 find any SNPs and only one SV, located in an intergenic region (> 30 Kb from next  
324 open reading frame), to be associated with growth rate and biomass (Table S12 and  
325 S13).

326       Among metabolic traits, we identified several loci that are associated with the  
327 contents of L-Glutamine, L-Tyrosine, L-Tryptophane, L-Serine, Chlorogenic acid and  
328 IAA. Most notably, several SNPs located within the *light harvesting protein 5*  
329 (*SpLHCB5*), which functions as a structural component of photosystem II (de Bianchi  
330 et al. 2008) were associated with contents of L-Glutamine, L-Valine, L-Tryptophan and  
331 L-Tyrosine (Figure 3 A-C, Table S13). Further, a SNP located upstream of a *U-box*  
332 *containing protein 4* (*SpPUB4*), which functions as a regulator of cell division  
333 processes in meristematic regions (Kinoshita et al. 2015), was associated with L-  
334 Tyrosine content. Three SNPs associated with the contents of L-Tyrosine, Chlorogenic  
335 acid and IAA were linked to *SpUGT89B1*, *SpCYP71AU50* and *SpMYBC1*, three genes  
336 functioning in secondary metabolite biosynthesis (Yamaguchi et al. 2014; Caputi et al.  
337 2012; Ke et al. 2021) (Figure 3 B, D, E). A SNP within *SpDPE2*, which is functionally

338 involved in starch metabolism is associated with IAA content (Li et al. 2022) (Figure  
339 3E). For SVs, contents of L-Glutamine and L-Serine were associated with a 94 bp  
340 intronic deletion in the *Ubiquitin-carboxyterminal hydrolase 7 SpUBP7* (Figure 4A-C).  
341 Homologs of *SpUBP7* were shown to stabilize ubiquitin upon proteasome binding and  
342 regulate proteasomal activity (Leggett et al. 2002; Wu et al. 2019). The presence of  
343 the intronic deletion was associated with increased contents of L-Glutamine and L-  
344 Serine (Figure 4D and E) and an increased expression of *SpUBP7* in roots (Figure 4F  
345 and G). These findings suggest that biomass and metabolite contents are coordinated  
346 jointly through photosynthesis, starch metabolism, cell division, secondary metabolite  
347 biosynthesis and protein degradation.

348

## 349 **Discussion**

350 Using targeted metabolomics on 137 *S. polyrhiza* genotypes, we identified strong  
351 positive correlations between chemically related metabolites. Additionally, candidate  
352 genes involved in photosynthesis (*SpLHCB5*), protein degradation (*SpUBP7*) and  
353 organ development (*SpLOB*, *SpAGL62*) were repeatedly associated with different  
354 metabolite levels, suggesting strong genetic co-regulation. Since levels of free amino  
355 acids and secondary metabolites correlated with plant biomass in many cases, some  
356 of these candidate genes are of potential use for joint optimization of plant growth and  
357 nutrient level.

358 Free amino acids have large pool sizes and turnover rates in duckweed and  
359 were shown to serve as major carbon and nitrogen sources for starch and storage  
360 protein production (Evans et al. 2018). Previous work showed that supplementation of  
361 growth medium with certain amino acids like L-Glutamine was associated with  
362 increased protein content and biomass in duckweed (Shi et al. 2023). In agreement  
363 with these observations, the associations between free amino acid levels and biomass

364 are mostly positive. Compared to free amino acids, phenylpropanoids and  
365 phytohormones are characterized by a higher functional diversity. In *S. polyrhiza*,  
366 anthocyanins were shown to alleviate Cr(VI) stress (Oláh et al. 2009), whereas  
367 luteolins and apigenins are involved in stress responses to copper and UV-light,  
368 respectively (Böttner et al. 2021). Previous studies found the contents of these three  
369 flavonoid classes to be inversely correlated with biomass in *S. polyrhiza* (Böttner et al.  
370 2021; Oláh et al. 2009) and explained this by increased allocation of carbon resources  
371 to flavonoid biosynthesis (Oláh et al. 2009). Compared to this, our study revealed a  
372 more diverse association pattern of flavonoid levels with biomass. While the contents of  
373 Sinapic acid, luteolins and Cyanidin-3O-glycoside were negatively associated with  
374 biomass, contents of Apigenin-8-C-glycoside and Chlorogenic acid showed positive  
375 correlations with biomass. In other plant species, changes in profiles of glycosylated  
376 flavonoids were shown to regulate plant growth by influencing auxin transport (Ringli  
377 et al. 2008), possibly explaining different association patterns of glycosylated luteolins  
378 and apigenins to plant biomass. Contents of chlorogenic acid were associated with  
379 increased leaf growth and increased contents of antioxidants and proteins, suggesting  
380 a regulatory function in plant growth (Zhang et al. 2024). The overall positive  
381 associations of cytokinin levels with most phenylpropanoids, were previously explained  
382 by their function in coordinating resource allocation to defense metabolism in plant  
383 development (Brütting et al. 2017). For phytohormones, levels of JA-Ile were positively  
384 correlated with biomass. In duckweeds, jasmonates show bimodal dose-response  
385 patterns, with small concentrations stimulating growth and turion germination and high  
386 concentrations delaying growth (Appenroth et al. 1991; Piotrowska et al. 2010). Since  
387 metabolites were measured in unstressed plant material, JA contents likely never  
388 exceeded constitutive levels, which would be required for significant growth inhibition.

389 Together these correlation patterns suggest that *S. polyrhiza* can be simultaneously  
390 optimized for higher biomass and increased contents of certain phenylpropanoids.

391 On a genetic level, our study identified genetic loci that are associated with most  
392 secondary metabolite and phytohormone contents, whereas for many free amino  
393 acids, no significant associations were found. For growth rate and biomass, we did not  
394 find significant associations for any markers located within the genic region, likely due  
395 to their highly polygenic feature. Previous GWAS conducted on complex traits  
396 highlighted, that the success in identifying genetic associations greatly depends on  
397 sample size and phenotypic variation (Schizophrenia Working Group of the Psychiatric  
398 Genomics Consortium 2014; Duncan et al. 2019; Chen et al. 2014). In line with  
399 previous reports (Chen et al. 2016; Pham et al. 2023), we found that secondary  
400 metabolite levels showed the highest average phenotypic variation across all  
401 metabolic traits, whereas variation for growth parameters was lowest. For secondary  
402 metabolites, high variation in tissue concentration was explained by their low trait  
403 complexity (Pham et al. 2023; Haghi et al. 2022; Chen et al. 2014). Whereas primary  
404 metabolites and growth seem to be regulated by many small effect loci, secondary  
405 metabolites are often controlled by just a few major-effect loci (Chen et al. 2014; Chen  
406 et al. 2016). Since small effect loci are often diffusely distributed across the genome,  
407 GWAS on primary metabolite levels and growth often require large sample sizes to  
408 detect them (Duncan et al. 2019). Compared to other association studies on plant  
409 metabolic traits (Chen et al. 2014; Chen et al. 2016; Cu et al. 2021; Angelovici et al.  
410 2013), our GWAS suffered from a low sample size, likely explaining the lack of genetic  
411 associations for growth traits and several metabolite contents.

412 On a physiological level, differences in growth were correlated with the  
413 photosynthesis rate for duckweed (Sree et al. 2015). Connected to this, the metabolism  
414 of storage molecules plays a major role in plant growth. Interestingly, many biomass-

415 correlated metabolites were associated with genes influencing photosynthetic  
416 efficiencies (*SpLHCB6*), protein turn over (*SpUBP7*), starch metabolism (*SpDPE*) or  
417 cell-cycle control (*SpPUB4*). These genes provide suitable candidates for future  
418 reverse genetic studies, that will be required for further elucidation of their exact  
419 function in duckweed metabolism. Taken together, this study provides insights into the  
420 molecular basis of growth regulation and metabolite homeostasis in *S. polyrhiza*.  
421 Through the identification of gene candidates associated with metabolic traits, this  
422 study contributes to laying the foundations for further optimization strategies in *S.*  
423 *polyrhiza*.

424

## 425 **Acknowledgement**

426 We thank Marie Serwaty-Sárazová for maintaining the giant duckweed collection.

## 431 **Main Tables**

432 Table 1: Phenotypic variation and heritability of fitness parameters in *S. polyrhiza*

Fitness trait	Mean	SE	Range		Fold change	H2.c
			Minimum	Maximum		
Fresh weight	227.7 mg	7.3 mg	71.6 mg	507.7 mg	10.4	0.865
Dry weight	16.67 mg	0.5 mg	3.4 mg	35.2 mg	10.4	0.602
RGR of frond area	0.323 d <sup>-1</sup>	0.004 d <sup>-1</sup>	0.165 d <sup>-1</sup>	0.401 d <sup>-1</sup>	2.4	0.841
RGR of frond number	0.259 d <sup>-1</sup>	0.003 d <sup>-1</sup>	0.152 d <sup>-1</sup>	0.328 d <sup>-1</sup>	2.2	0.802

433 Abbreviations: SE - standard error, H2.c – broad sense heritability according to Cullis

434 et al. (2006)

435 **Main Figures**

436

437

438

439 **Figure 1: Overview of the biosynthesis of metabolites analyzed in this study.**

440 Metabolites were connected to their biochemical precursors with arrows. All quantified  
441 compounds were sorted into the three categories amino acid metabolism, specialized  
442 metabolism and phytohormones and shown in boxes colored red, blue, and green,  
443 respectively. Direct degradation products and biosynthetic precursors of amino acids  
444 such as tyramine and shikimic acid were grouped together with all quantified amino  
445 acids in the group amino acid metabolism. Amino acids were subcategorized into five  
446 families based on their last common precursor (serine, pyruvate, aspartate and  
447 glutamate) or on common chemical properties (aromatic amino acids). All specialized  
448 metabolites quantified in this study are phenylpropanoids derived from phenylalanine.  
449 Phenolic acids are also precursors of flavonoids. In contrast to amino acids and  
450 secondary metabolites, compounds with a major function in signalling were  
451 characterized as phytohormones. Chemically derived metabolites with the same

452 precursors were further grouped in biosynthetic families, illustrated by frames of  
453 different colors.

454 Abbreviations: TCA – tricarboxylic acid, iP – Isopentenyladenine, iPR –  
455 Isopentenyladenine riboside, tZ – trans-Zeatin, cZ – cis-Zeatin, tZR – trans-Zeatin  
456 riboside, cZR – cis-Zeatin riboside, 3-PGA – 3-Phosphoglycerate, PEP –  
457 Phosphoenolpyruvate, CoA - Coenzyme A, E4P – Erythrose-4-phosphate, R5P –  
458 Ribose-5-phosphate, DAHP – 3-Deoxyarabinoheptulonate-7-phosphate, JA –  
459 Jasmonic acid, JA-Ile – Jasmonic acid-Isoleucine conjugate, IAA – Indole-3-acetic  
460 acid, SA – Salicylic acid, ABA – Abscisic acid

461

462

463

464

465 **Figure 2: Correlation matrix (A) and principal coordinate analyses (PCA) on**  
 466 **growth parameters (B) and metabolite content (C).** A: Tissue concentrations of  
 467 amino acids showed strong positive correlation patterns. In most cases, contents of  
 468 amino acids were positively correlated with flavonoid content and biomass. Metabolite  
 469 concentrations and growth rates were measured for 137 genotypes. All metabolites  
 470 were categorized according to Figure 1. The strength of the correlation was  
 471 estimated using tPearson correlation coefficient and is reflected by the intensities of

472 red color for positive and blue color for negative correlations. Asterisks highlight  
473 significant correlations ( $F$ -test,  $P < 0.05$ ). Simultaneous correlations of dry and fresh  
474 weight were highlighted with red margins. B and C: population differences on growth  
475 (B) and metabolisms (C). All PCAs were conducted on 97 representative genotypes  
476 assigned to four previously defined genetic populations (Xu et al. 2019). The ellipses  
477 show 95 % confidence intervals calculated based on standard deviation. The color of  
478 the ellipses corresponds to the genetic populations. Abbreviations: iP –  
479 Isopentenyladenine, iPR – Isopentenyladenine riboside, tZ – trans-Zeatin, cZ – cis-  
480 Zeatin, tZR – trans-Zeatin riboside, cZR – cis-Zeatin riboside, JA – Jasmonic acid, JA-  
481 Ile – Jasmonic acid-Isoleucine conjugate, IAA – Indole-3-acetic acid, SA – Salicylic  
482 acid, ABA – Abscisic acid  
483  
484

485

486 **Figure 3: Manhattan plots of SNP-based GWAS for free amino acids.** Each plot

487 shows the GWAS result on the concentrations of L-Glutamine (A), L-Tyrosine (B), L-

488 Tryptophan (C) and Chlorogenic acid (D) and Indole-3-acetic acid (IAA) (E) with their  
 489 corresponding QQ-plots on the right side. The Bonferroni corrected  $P$ -value = 0.05  
 490 (Wald-test) at  $4.97 \cdot 10^{-6}$  was used as significance threshold and is shown as red line.  
 491 All significant markers are labelled with the names of gene candidates.  
 492

493

494 **Figure 4: The presence of an intronic deletion in *SpUBP7* is associated with**  
495 **increased contents of L-Glutamine and L-Serine.** A and B: The SV-based GWAS  
496 on L-Glutamine (A) and L-Serine (B). The red line represents the Bonferroni corrected  
497 *P*-value = 0.05 (Wald-test) at  $4.23 \cdot 10^{-5}$ . C: The associated 94 bp deletion (red bar) is  
498 located within the 7<sup>th</sup> intron of *SpUBP7*. D and E: The presence of the deletion was  
499 associated with increased contents in L-Glutamine (D) and L-Serine (E). F: *SpUBP7*  
500 shows genotype-dependent expression differences on root level. SP187, a genotype  
501 that is homozygous for the deletion, shows enhanced *SpUBP7* expression compared  
502 to genotype SP012 that lacks the deletion. G: No significant differential expression was  
503 observed between SP187 and SP012 in the fronds.

### 3.3 Population Genomics and Epigenomics of *Spirodela polyrhiza* Provide Insights into the Evolution of Facultative Asexuality

#### 3.3.1 Summary

The focus of this study lies in the characterization of the genomic/epigenomic diversity, population structure and migration history of *Spirodela polyrhiza*.

The genomes of 228 sequenced genotypes of *S. polyrhiza* were used to identify SNPs, insertions/deletions (< 50bp) and structure variations (> 50bp). CpG, CHH and CHG - methylation levels were determined through bisulfite sequencing of five genotypes from each genetic population of *S. polyrhiza*. SNPs were used to infer of population structure via PCA and phylogeny, applying a maximum-likelihood approach. The demographic history of the genetic populations of *S. polyrhiza* was predicted using an Approximate Bayesian Computation (ABC) approach. A genome-wide selection scan was used to discover genomic regions under positive selection.

This study identified a total of 1241981 SNPs, 166075 insertions/deletions and 3205 structure variations. The identified genome-wide nucleotide diversity of *S. polyrhiza* was 0.0016. Further, *S. polyrhiza* was shown to have the lowest average species-wide methylation rate among all studied angiosperms. Analysis of population structure identified four genetic populations, which were largely defined by their geographic locations as American, SE-Asian, Indian and European populations. Approximate bayesian computation modelling predicts that American and SE-Asian populations are derived from a common ancestral population. Indian and European populations later diverged from the SE-Asian population. Populations differed regarding their linkage-disequilibrium decay and heterozygosity rate, suggesting differences in rates of sexual reproduction. Different levels of heterozygosity were associated with two MADS-box genes: *AGL62* and *SOCI*, whose orthologs control the development of floral organs. A genome-wide scan identified 69 genes whose homologs function predominantly in processes such as gametogenesis, embryogenesis, flowering time and organ development to be under selection. Many genes involved in reproduction and organ development, like *BB*, *FLK*, *AGL6* and *AP3* were under selection in the European or Indian population.

Together, this study suggests that natural selection shapes the plants reproduction mode and organ development, explaining strong population-specific variations in genetic and epigenetic markers.

### 3.3.2 Zusammenfassung

Diese Studie charakterisiert die genetische/epigenetische Variation, sowie die Demographie und Migrationsgeschichte von *Spirodela polyrhiza*. Hierfür wurden die Genome von insgesamt 228 *S. polyrhiza* Genotypen zur Identifikation von SNPs, Insertionen/Deletionen (<50 bp) und strukturelle Variationen (>50 bp) gefiltert. Cytosinmethylierungen (CpG, CHH und CHG) wurden mittels Bisulfidsequenzierung von jeweils fünf Genotypen aus jeder genetischen Population von *S. polyrhiza* identifiziert. Demographische oder phylogenetische Analysen wurden mittels PCA oder Maximum-likelihood basierenden Methoden auf Basis von SNP-Daten durchgeführt. Migrationsprozesse der verschiedenen Populationen wurde mittels Approximate bayesian computation vorhergesagt. Genomische Regionen, welche Ziel von Selektionsereignissen waren, wurden in einem Genom-weiten Scan auf Basis von SNP-Daten identifiziert. Insgesamt wurden in dieser Studie 1241981 SNPs, 166075 Insertionen/Deletionen und 3205 strukturelle Variationen identifiziert. Die Genom-weite Nukleotid-Diversität betrug 0.0016. Weiterhin konnte für *S. polyrhiza* die niedrigste durchschnittliche Spezies-weite Methylierungsrate innerhalb aller analysierter Angiospermen ermittelt werden. Durch Analyse der Populationsstruktur wurden insgesamt vier genetische Populationen, welche nach ihren überwiegenden Verbreitungsgebieten als Amerika, SO-Asien, Indien und Europa Populationen bezeichnet worden sind, identifiziert. Gemäß der Vorhersage des Approximate bayesian computation -Modells, ist ein Szenario, bei dem die Amerika und SO-Asien Populationen einer gemeinsamen Urpopulation entspringen und die Indien und Europa Populationen sich später aus der SO-Asien Population entwickelt haben am wahrscheinlichsten. Genetisch unterschieden sich die Populationen hinsichtlich der Größe ihrer Kopplungsblöcke und ihres Heterozygotiegrades, was auf Unterschiede in der sexuellen Reproduktionsrate zurückzuführen sein könnte. Unterschiede im Heterozygotieindex wurden mit zwei MADS-box Genen: *AGL62* und *SOCI*, deren Orthologe die Entwicklung von Blütenorganen steuern, assoziiert. Ein Genom-weiter Scan identifizierte 69 Gene, welche Ziel von Selektionsereignissen waren. Homologe dieser Gene sind funktional vorwiegend an Prozessen wie Gametogenese, Embryogenese, Blühinduktion und Organentwicklung beteiligt. Viele Gene, die an Reproduktions- oder Entwicklungsprozessen beteiligt sind wie *BB*, *FLK*, *AGL6* und *AP3* standen in der Europa- oder Indien-Population unter Selektion. Zusammenfassend liefert dieses Studie Erkenntnisse darüber, wie natürliche Selektion reproduktive Eigenschaften und Entwicklungsprozesse formen kann. Aus derartigen Selektionsprozesse resultieren starke Populations-spezifische Unterschiede in der Verteilung genetischer und epigenetischer Marker.

### 3.3.3 Statement of Contribution

The project was supervised by Meret Huber and Shuqing Xu. All data analyses were conducted by Yangzi Wang, Pablo Duchén and Shuqing Xu. Klaus-Jürgen Appenroth, Sowjanja Sree, Hai Zhao and Shuqing Xu provided duckweed genotypes and further resources to the project. Alexandra Chávez conducted all DNA extractions and DNA sample preparations. Martin Höfer conducted RNA-extractions and generated cDNA libraries used for confirming the expression of the identified candidate genes via qPCR in two genotypes. Shuqing Xu, Yangzi Wang, Pablo Duchén, Alexandra Chávez and Meret Huber wrote the first draft of the manuscript and prepared all figures. All authors provided feedback on the final version of the manuscript or contributed to the supplemental part of the manuscript.

# Population genomics and epigenomics of *Spirodela polyrhiza* provide insights into the evolution of facultative asexuality

Yangzi Wang<sup>1,2,8</sup>, Pablo Duchén<sup>1,2,8</sup>, Alexandra Chávez<sup>1,2,3</sup>, K. Sowjanya Sree<sup>4</sup>, Klaus J. Appenroth<sup>5</sup>, Hai Zhao<sup>6</sup>, Martin Höfer<sup>1,2</sup>, Meret Huber<sup>1,3</sup> & Shuqing Xu<sup>1,2,7</sup> ✉

Many plants are facultatively asexual, balancing short-term benefits with long-term costs of asexuality. During range expansion, natural selection likely influences the genetic controls of asexuality in these organisms. However, evidence of natural selection driving asexuality is limited, and the evolutionary consequences of asexuality on the genomic and epigenomic diversity remain controversial. We analyzed population genomes and epigenomes of *Spirodela polyrhiza*, (L.) Schleid., a facultatively asexual plant that flowers rarely, revealing remarkably low genomic diversity and DNA methylation levels. Within species, demographic history and the frequency of asexual reproduction jointly determined intra-specific variations of genomic diversity and DNA methylation levels. Genome-wide scans revealed that genes associated with stress adaptations, flowering and embryogenesis were under positive selection. These data are consistent with the hypothesis that natural selection can shape the evolution of asexuality during habitat expansions, which alters genomic and epigenomic diversity levels.

Understanding the evolution of sexual reproduction has long been at the center of evolutionary biology. Theories suggest that asexual reproduction is beneficial for the short term but costly for the long term, mainly due to accumulations of deleterious mutations and low effective population size<sup>1–5</sup>. Facultative asexuality, where organisms can reproduce both sexually and asexually depending on environmental conditions, should be optimal for one individual's lifespan<sup>6,7</sup>. While rather few animals such as aphids (Aphidoidea)<sup>8</sup>, water fleas (Cladocerans)<sup>9</sup>, and rotifers<sup>10</sup> reproduce facultatively asexually, up to ~80% of the flowering plants, including important crops and keystone species, can reproduce both sexually and asexually<sup>11</sup>. Asexual reproduction in plants involves different types of vegetative reproduction (e.g. runners, tubers, bulbs, corms, suckers, plantlets), as well as apomixis, the formation of seeds without fertilization<sup>12</sup>. Because changes between sexual and asexual reproduction affect the ability to persist in the short and long term, natural selection might act on the genetic controls of sexual and asexual reproduction in facultative asexual organisms, which in turn can alter the levels of genomic diversity, heterozygosity and effectiveness of selection in the population<sup>2,5,13–15</sup>. However, direct evidence

supporting this prediction remains scarce, mainly due to the lack of a suitable facultative asexually reproducing system in which the signature of selection can be detected at genomic levels.

Evolutionary changes in sexual and asexual reproduction might also affect the maintenance and dynamics of chromatin marks, e.g. epigenetic markers such as DNA methylations. In plants, cytosine methylation can occur in three sequence contexts: CpG, CHG, and CHH (H = A, T, or C), which are controlled by different mechanisms and have different dynamics during reproduction<sup>16</sup>. Typically, CpG and CHG methylation are maintained by methyltransferases1 (*MET1*) and CHROMOMETHYLASE3 (*CMT3*), respectively, whereas CHH methylation is mostly maintained by *CMT2*<sup>17</sup>. During sexual reproduction, DNA methylations are highly dynamic<sup>18</sup>. In both male and female gametogenesis, the megaspore mother cell and microspore mother cell experience dramatic chromatin changes during cell specification, such as heterochromatin decondensation and an enlarged nuclear volume<sup>19,20</sup>. During male gametogenesis, sperm DNA is highly methylated in the CpG and CHG context but has low CHH methylation in retrotransposons<sup>18,21,22</sup>. During female gametogenesis, CpG

and CHH methylation remains largely steady<sup>23</sup>. After fertilization, CHH methylation increases during embryogenesis and can approach 100% at individual cytosines, which then decreases likely through a passive mechanism after germination<sup>24–26</sup>. In contrast, during vegetative reproduction, DNA methylation is likely steady since meiosis and embryogenesis are lacking<sup>27–29</sup>. Although Niederhuth, C. E. et al.<sup>30</sup> comparing DNA methylations among 34 angiosperm species suggested that clonally propagated species often have low CHH methylation, the extent to which asexual reproduction affects genome-wide methylation levels remains unclear.

Here, we investigated the population genome and epigenome of a facultatively asexual plant, *Spirodela polyrhiza* (the giant duckweed; Lemnaceae), using samples from a global collection. This species, like other duckweeds from the genera *Spirodela*, *Landoltia* and *Lemna*, is characterized by leaf-like fronds derived from fused stems<sup>31</sup> and, with multiple roots on each frond<sup>32</sup> and with a highly reduced vascular system<sup>33</sup>. *Spirodela polyrhiza* reproduces vegetatively via budding under normal conditions but very rarely switches to sexual reproduction under unfavorable conditions<sup>34,35</sup>. Recent studies showed that despite its global distribution in diverse habitats, the genomic diversity, spontaneous mutation rates and DNA methylation levels in *S. polyrhiza* are very low<sup>36–41</sup>, which might be associated with its overall low frequency of sexual reproduction. DNA methylation profiling of two genotypes suggests that DNA methylation in *S. polyrhiza*, which is substantially lower than in other plants, varied between genotypes<sup>41</sup>. Further insights into the evolutionary origin and consequences of asexuality on genomic and epigenomic variation in *S. polyrhiza* are required to understand the demographic history and to identify the footprint of selection on the genome.

## Results

### Extremely low genomic variations in *S. polyrhiza*

We sequenced the genomes of 131 globally distributed *S. polyrhiza* genotypes with an average of ~25 X coverage. Together with previously published samples<sup>36,37</sup>, we analyzed the genomic diversity of 228 *S. polyrhiza* individuals across five continents (Supplementary Data 1). We identified 1,241,981 high-quality biallelic single-nucleotide polymorphisms (SNPs) and 166,075 short insertions and deletions (INDELs, less than 50 bp of length). Based on an updated genome annotation of *S. polyrhiza* (see Supplementary Results Methods 1.1 and Supplementary Results Section 2.1), we found that most of the SNPs (70.3%) are in the intergenic regions (Supplementary Fig. 1). Of all the SNPs located in the protein-coding regions, 61,039 were identified as nonsynonymous and 44,287 as synonymous (Supplementary Data 2). Consistent with our previous study<sup>36</sup>, the genome-wide nucleotide diversity is 0.0016 (Supplementary Table 1), which falls within the lower range of genome-wide nucleotide diversity of other tested multicellular eukaryotes (Supplementary Table 2 and Supplementary Fig. 2). The species-wide efficacy of selection ( $\pi_N/\pi_S$  ratio) is 0.37, the highest among studied organisms<sup>42</sup>, indicating a relatively relaxed purifying selection in *S. polyrhiza*, despite its large effective population size<sup>36,37</sup>.

In addition to SNPs and small INDELs, we also characterize the genome-wide structural variations (SVs,  $\geq 50$  bp in length) in *S. polyrhiza* (see Supplementary Methods Section 1.2 and Supplementary Results Section 2.2). We identified 3,205 high-quality SVs, including 2,089 deletions, 291 duplications, and 825 insertions. Among all identified SVs, 155 duplications and 169 deletions affected protein-coding sequences (Supplementary Table 3 and Supplementary Data 3). Using a permutation approach at a genome-wide level, we identified gene families that are significantly enriched with SVs and small INDELs (see Supplementary Methods Section 1.3, 1.4, and 1.5, Supplementary Results Section 2.3, and Supplementary Data 4 and 5), respectively. We found several gene families related to defences, such as *RPP8*<sup>43</sup> and the glycoside hydrolase<sup>44</sup>, are enriched with both SVs and small INDELs. This is consistent with findings from *Arabidopsis* and other plant species, which show that SVs are enriched in stress and pathogen resistance<sup>45,46</sup> (Supplementary Data 5). Interestingly, we also found SVs and small INDELs are also enriched in gene families that are involved in organ development and reproduction, such as the receptor-like

protein kinases gene family<sup>47</sup> and MADS-box gene family that has been shown to have substantial gene losses and copy number variations in duckweeds<sup>48–50</sup>.

### Population structure and demographic history of *S. polyrhiza*

Because *S. polyrhiza* is facultatively asexual, genotypes collected from the geographic proximity can be derived from the same clonal family. Using a previously established grouping threshold that was developed in *S. polyrhiza*<sup>2</sup>, we identified 159 likely clonal families in the sampled population (Supplementary Data 6).

Population structure and principal component analyses revealed four populations in the sampled *S. polyrhiza* (Fig. 1a and b). Consistent with our previous study, the four populations are largely concordant with their geographic origins, namely America, Southeast Asia (SE-Asia), Europe, and India (Supplementary Fig. 3), with a few exceptions that can be due to recent migration events or artifacts during long-term duckweed maintenance.

We inferred the population history with a Maximum Likelihood (ML) phylogeny and Approximate Bayesian Computation (ABC). For ML, we used *Colocasia esculenta* (from the Araceae family) as an outgroup. The maximum likelihood phylogeny of all 228 genotypes indicated an early split of the American population from the other populations and subsequent splits of the Indian and European populations from SE-Asia (Fig. 1c). The European population constitutes the most recent split (Fig. 1c and d). Here, genotypes collected from the transcontinental region (e.g. Russia) showed intermediate features of SE-Asian and European populations, suggesting this as a likely migration route. Furthermore, the Indian population possibly originated via Thailand and Vietnam, as genotypes from these countries show intermediate features between Indian and SE-Asian populations.

We modeled the demographic history using an ABC modeling approach to further validate the evolutionary history of the four populations in *S. polyrhiza* (see Supplementary Methods Section 1.6 and Supplementary Table 4). Based on the phylogenetic analysis, we simulated three plausible demographic scenarios, allowing for either the SE-Asian, American or an additional putative population to function as the ancestral population (Supplementary Fig. 4). We found that the scenario, in which the American population and Asian population were derived from an additional putative ancestral population, constituted the most supported model (Fig. 1d). While the American population was separated from other populations around one million generations ago, the European population was derived from the SE-Asian population only 12,000 generations ago (see Supplementary Results Section 2.4 and Supplementary Table 5).

### Determinants of genomic diversity among populations

Among the four populations, nucleotide diversity ( $\pi$ ) and the efficacy of selection ( $\pi_N/\pi_S$  ratio) varied among populations (Fig. 2b). While the SE-Asian population has the highest  $\pi$  and lowest  $\pi_N/\pi_S$  ratio, the American population has the lowest  $\pi$  and highest  $\pi_N/\pi_S$  ratio. Interestingly, while the European population has a much smaller  $\pi$  compared to the SE-Asian population, the  $\pi_N/\pi_S$  ratio of the European population remains similar to the latter, likely due to its recent split from the SE-Asian population.

Using genome-wide SNPs, we found that linkage disequilibrium (LD) is comparable to *Arabidopsis thaliana*<sup>51</sup>, suggesting considerable historical sexual reproduction in *S. polyrhiza*. However, the extent of LD decay varied substantially among populations (Fig. 2b and Supplementary Fig. 5). While the Asian population showed the most rapid LD decay (about 12 kb at  $r^2 = 0.2$ ), the European population had very long LD blocks (>100 kb). The Indian and American populations had intermediate LD decay. Consistently, the Asian population had the highest recombination rate compared to the other three (Fig. 2b). Different LDs and recombination rates found among populations indicate that the frequencies of sexual reproduction varied among populations. In addition, we found that the variations of heterozygosity in *S. polyrhiza* showed a similar pattern with the genomic diversity and recombination rate among four populations (Fig. 2b and Supplementary Fig. 6).

**Fig. 1 | Phylogeny, population structure and demographic model of 228 *S. polyrhiza*.** **a** The population structure of 228 *S. polyrhiza* genotypes. **b** The principal component (PC) analysis of the SNPs from 228 *S. polyrhiza* genotypes. The three coordinates indicate the first three PCs. **c** The Maximum Likelihood phylogenetic

tree of 228 *S. polyrhiza* genotypes. The gray branch represents the outgroup - *C. esculenta*. Dashed branches represent internal nodes with supporting values lower than 0.75 (the max is 1). **d** The demographic model of *S. polyrhiza* populations. “ $T_{\text{population}}$ ” indicates the estimated divergence time in generations.

Interestingly, the changes in genomic diversity and levels of heterozygosity are associated with two SVs involving MADS-box genes that are involved in sexual reproduction. One SV is an 84 bp insertion at the last coding sequence (CDS) of gene SpGA2022\_005278, a homolog of *AGL62* from the  $M\alpha$  subclade of MADS-box genes (Supplementary Fig. 7). In *A. thaliana*, *AGL62* is a transcription factor that suppresses endosperm cellularization by activating the expression of a putative invertase inhibitor, *InvINH1*, in the micropylar region of the endosperm<sup>52,53</sup> (Supplementary Fig. 8). The insertion may potentially disrupt the function of the *AGL62*-like gene, suggesting a possible reduction in the suppression of endosperm development, which might be required for sexual reproduction (Fig. 2a). Consistently, we found the insertion was at a higher abundance in the SE-Asian population (87.5%) than in other populations (Fig. 2c, d). In addition, the insertion positively correlates with heterozygosity within the European population (Supplementary Table 6 and Supplementary Fig. 9).

Another SV is a 69 bp deletion at 1.8 kb upstream of SpGA2022\_007306, (Supplementary Fig. 7), a gene that show homology to *SOC1* (but shorter than *SOC1*, Supplementary Data 7), which is a positive regulator of the flowering process in *A. thaliana*<sup>54</sup> (Fig. 2a). Conserved protein domain analyses suggested that SpGA2022\_007306 has *SRF*-like MADS domain but lacks the K-box region (Supplementary Fig. 10), which is similar to *Os03g03100* (*OsMADS50*), a *SOC1* homology that are involved in regulating flowering time in rice<sup>55–58</sup>. The deletion was exclusively found in the Indian population with the alternate allele frequency of 73% (Fig. 2c). It is plausible that the deletion, due to its disruption potential at the *cis*-regulatory region, reduces the ability of this *SOC1*-like gene to respond to the upstream floral activators (e.g. *CO*) in *S. polyrhiza*, thus reducing the frequency of sexual reproduction in the Indian population (Fig. 2d). Consistently, this deletion negatively correlates with heterozygosity in the Indian population (Supplementary Table 6, Supplementary Fig. 11). However,

future functional validations on SV of the two MADS-box genes are needed to provide further mechanistic insights into the observed patterns.

### Population epigenomic diversity in *S. polyrhiza*

As changes in sexual reproduction can also alter epigenomic dynamics, we further investigated the patterns of population epigenomic diversity in *S. polyrhiza*. We selected five individuals from each population and quantified their shoot DNA methylation levels at single-base resolution using whole genome bisulfite sequencing (Supplementary Table 7). Similar to a recent study<sup>39</sup>, we found that only 1.6% of cytosines are methylated in *S. polyrhiza* (7.6% of CpG, 2.3% of CHG, and 0.1% of CHH; Supplementary Table 8), and the average species-wide methylation level is the lowest among all studied angiosperms (Supplementary Fig. 12)<sup>30,59</sup>. The hierarchical clustering of 20 methylomes in CHG and CHH contexts in gene bodies show overall consistency with their genetic similarity (Supplementary Fig. 13 and 14) with few discrepancies were mostly found within the same population or between the recently diverged SE-Asian and European populations. While in the CpG context, we did not observe clear correlations between genetic and methylation distances (Supplementary Fig. 15).

We then compared the genome-wide weighted methylation level (wML) among populations. For CpG methylation, no differences were found among four populations at genome-wide, gene body, or TE levels (Fig. 3a, d and g). For CHG, the Indian population had the lowest genome-wide methylation level among all four populations (Fig. 3b, e, and h). Interestingly, for CHH, the SE-Asia and Europe populations had the higher genome-wide methylation levels compared to American and India populations ( $P < 0.05$ , pairwise Wilcoxon test; Fig. 3c), while the European and Indian populations showed a gradual reduction of methylation in comparison to the SE-Asian population. The pattern was the same for both gene

**Fig. 2 | Genomic diversity variation among four populations might result from the switching between sexual and asexual propagation in *S. polyrhiza*.** **a** Scheme of asexual and sexual propagation cycles in *S. polyrhiza*. (A) Vegetative stage of *S. polyrhiza*; (B) Budding; (C) Offspring from clonal propagation; (D) *S. polyrhiza* flowering; (E) Putative schematic of ovule at endosperm cellularization stage; (F) Putative schematic of seeds. **b** Bar plots show the differences among the four populations in terms of “ $\pi$ ”: genome-wide nucleotide diversity; “LD”: the physical extent (in kb) of pairwise SNPs at  $r^2$  of 0.2 (Europe does not yet reach  $r^2 = 0.2$  at 100 kb, Supplementary Fig. 5); “ $\pi_N/\pi_S$ ”: the efficacy of linked selection; “ $r$ ”: genome-wide recombination rate; “H”: the median of per population genome-wide heterozygosity rate. **c** Two panels of pie charts indicate the allele frequencies of the functional allele of *SOCI*-like and *AGL62*-like genes among populations. Gray: functional allele frequency; Black: SVs allele frequency. **d** The distribution and migration world map of the four *S. polyrhiza* populations. “+” suggests the increased functional allele frequency, while “-” suggests the decreased functional allele frequency.

bodies and TEs ( $P < 0.05$ , pairwise Wilcoxon test; Fig. 3f, i). The genome-wide reduction of CHH methylation is consistent with the hypothesis that clonal reproduction reduces CHH methylation, and the effects gradually accumulate over clonal generations<sup>60</sup>.

**The footprint of selection on the genome**

To identify the genomic signature of selection at the species level, we performed genome-wide scans. To reduce false positives, we used the  $\mu$ -statistics from RAiSD<sup>61</sup>, the composite likelihood ratio CLR statistic from SweeD<sup>62</sup>, and the T statistic from LASSI<sup>63</sup>. We found 69 genes showed strong signatures of selection using all three methods (Supplementary Fig. 16 and Supplementary Data 8). Manual inspection indicated that several orthologs of these genes are related to gametogenesis (e.g., *NOTCHLESS*) and embryogenesis (e.g., *NUP214*, *CPSF*, *CDK*, *AGP*, and *ACR4*) in *Arabidopsis thaliana*<sup>64–68</sup>. Further enrichment analysis indeed showed that embryo lethal genes were enriched in these 69 genes ( $P = 0.016$ ,  $\chi^2$  test). In addition, the *A. thaliana* orthologs of several genes under selection are also associated with controlling sexual reproduction, including floral development (*DRMY1* and *ACR4*)<sup>64,69</sup>, flowering time (*NF-Y AT2G27470*, *NF-YAT1G72830*, and *CPSF*), pollen development (*EFOP3*, *ELMOD*, and *CLC*)<sup>66,70–74</sup>, seed development (*NUP214*, *NF-Y AT2G27470* and *NF-YAT1G72830*, and *Transducin/WD40*)<sup>65,70,75</sup>. Furthermore, among these 69 genes, we also found several genes involved in leaf development and vascularity (*SECA2*, *RbgA*, *PHABULOSA/PHAVOLUTA*)<sup>76–78</sup>, light signaling (*NF-Y*, *CCR4-NOT*, and *PPP*)<sup>70,79,80</sup>, root development (*GEND1*, *WAVY*, and *ACR4*)<sup>64,81,82</sup>, DNA damage repair (*ATM* and *Xrcc3*)<sup>83,84</sup>, and stress tolerance (*phospholipase D*, *histone superfamily protein*, *RabGAP*, *FC1*, *NUDX2*) (Supplementary Data 8).

To further understand the selection that drove the evolution within individual populations, we identified the signature of positive selection in a three-population tree using patterns of linked allele frequency differentiation and calculating the corresponding composite-likelihood ratio (CLR, see Methods). In total, we found 1,883 genes on the SE-Asian branch, 593 genes on the Indian branch and 401 genes on the European branch (Fig. 4a; see Supplementary Results Section 2.6, and Supplementary Data 9) which showed strong signatures of selection (top 1% of CLR values). We did not find evidence supporting the hypothesis that differentially methylated genes were under positive selection (see Supplementary Methods Section 1.7, Supplementary Results Section 2.5, and Supplementary Data 10).

We found that genes under positive selection in the European branch are enriched with reproduction and development-related GO terms (Supplementary Fig. 17). Among these, SpGA2022\_013448, in chromosome 9, is an ortholog of FLOWERING LOCUS KH DOMAIN (*FLK*) that delays flowering by up-regulating *FLC* family members in *A. thaliana*<sup>85</sup>. This gene showed a strong signature of selection in the European branch but not in other branches (Fig. 4c, d). Similarly, SpGA2022\_006111, on chromosome 3, is an ortholog of the *A. thaliana* BIG BROTHER (*BB*) that negatively regulates floral organ size and is also under selection in Europe<sup>86</sup> (Fig. 4c).

In the SE-Asian population, we found that gene SpGA2022\_051517, a CHROMOMETHYLASE3 (*CMT3*) ortholog in *A. thaliana* that is likely associated with maintaining CHG methylation<sup>17</sup>, was under positive selection. This is consistent with the higher CHG methylation levels observed in the SE-Asian population when compared to the European and Indian populations (Figs. 3a, b). Within the Indian population, we found that five MADS-box genes have been under selection exclusively along this branch. Given that there are 43 MADS-box genes in the genome, the fact that five of

**Fig. 3 | Weighted methylation level (wML) among four populations.** a–c Box plots of genome-wide weighted methylation level (wML) in (a) CpG, (b) CHG, and (c) CHH context ( $N = 5$ ). Uppercase letters indicate statistical differences among populations using Wilcoxon test (with bonferroni method for multiple tests corrections). d–f wML in the gene body and its flanking 2 kb regions in (d) CpG, (e)

CHG, and (f) CHH context. g–i wML in TE and its flanking 2 kb regions in (g) CpG, (h) CHG, and (i) CHH context. The asterisks indicate significant differences between populations ( $P < 0.05$ ; Wilcoxon test), while “n.s.” indicates no significant difference.

them have been targeted by selection, constitutes a significant enrichment of such genes under selection ( $P = 0.0075$ , Fisher’s Exact test). For example, SpGA2022\_013078 is an homolog of AGAMOUS-LIKE6 (*AGL6*), which is involved in flower and meristem identity specification in rice<sup>87</sup>; SpGA2022\_052274, a homolog of *APETALA3* (*AP3*), is involved in the petal and stamen specification in *A. thaliana*<sup>88</sup>; and SpGA2022\_006905 belongs to the SHORT VEGETATIVE PHASE (*SVP*-group) which controls the time of flowering and meristem identity<sup>89</sup>.

We found 77 genes under positive selection (top 1% CLR values) in both the European and Indian populations (Fig. 4b), significantly more genes than expected by chance ( $P < 2.2e-16$ , Fisher’s Exact Test). Among these, gene SpGA2022\_055195, an ortholog to *CYP78A9* of cytochrome P450 monooxygenases in *A. thaliana*, belongs to a highly conserved gene family *CYP78A*. Previous studies in *A. thaliana* and other species found that *CYP78A9* plays a critical role in promoting cell proliferation during flower development and further impacts seed size<sup>90–92</sup>. In addition, the RNA-seq data indicates that *CYP78A9* is differentially expressed between India and Europe populations (see Supplementary Methods Section 1.8, Supplementary Results Section 2.7, and Supplementary Data 11). Overall, these data consistently suggest that genes involved in reproduction and development were under selection in Indian and European populations, which might have led to reduced sexual reproduction in these two populations.

### Discussion

Here, we characterized the genomic and epigenomic diversity, as well as the demographic history of a facultative asexual flowering plant, *S. polyrhiza*. We found that among populations of *S. polyrhiza*, demographic history and reproductive system jointly determine the population’s genomic and epigenomic diversity. Analyses on the footprint of selection

suggest that natural selection drove the reduced vascular system and increased asexuality in *S. polyrhiza*.

Theory predicts that asexual reproduction reduces genomic diversity and the efficiency of purifying selection<sup>93</sup>. Consistent with this prediction, at the species level, we found that *S. polyrhiza* has very low genomic diversity and reduced purifying selection (seen as an increased  $\pi_N/\pi_S$  ratio), when compared to a wide range of spermatophyte plants<sup>42</sup>. Within species, the SE-Asian population, which has the highest frequency of sexual reproduction based on the estimated recombination rate, has the highest genomic diversity, the lowest  $\pi_N/\pi_S$  ratio and the highest heterozygosity (Fig. 2b), supporting the theoretical prediction<sup>2,5,13–15</sup>. The low  $\pi_N/\pi_S$  ratio found in the European population, which has the lowest sexual reproduction and genomic diversity, is most likely due to its migration history. The demographic model suggested that the European population derived from the SE-Asian population very recently (Fig. 1d). It is likely that the  $\pi_N/\pi_S$  ratio in the European population remained the same as its ancestral population and has not reached an equilibrium level yet.

While there are fewer genome-wide SVs in *S. polyrhiza* compared to other species<sup>94,95</sup>, we found these variants and small INDELS are in tendency enriched in stress responses and reproduction, such as MADS-box genes. This indicates that the loss-of-function of genes involved in flower development and sexual reproduction, is under natural selection. The results are consistent with the observation that the number of functional MADS-box genes was dramatically reduced in *S. polyrhiza*<sup>49</sup>.

Single-base resolution methylomes of 20 individuals showed that the overall CpG, CHG and CHH methylation levels in *S. polyrhiza* shoots are very low, consistent with previous studies<sup>39,41</sup>. The low levels of DNA methylation might be associated with reduced sexual reproduction: while CpG and CHG methylations in plants are important for controlling cross-overs during

**Fig. 4 | Branch-specific selection signature scans.** **a** Population tree is used for the population-specific selection analyses. Input consists of an “outgroup” population (America) and two “ingroup” populations (India and SE-Asia, or Europe and SE-Asia). We present the number of genes in the ingroup populations belonging to the top 1% CLR scores reported by 3P-CLR. **b** Venn diagram showing the genes under selection that are common between the populations of SE-Asia, India, and Europe. **c** Branch-specific genome-wide scan of selection: each dot represents a chromosomal locus picked by 3P-CLR for which a CLR score is calculated; loci on the top 1%

CLR are shown in red. The dashed purple lines between European and Indian panels indicate common peaks of selection detected at the same genomic regions in both populations. **d** Genomic diversity as depicted by  $\pi$  (solid black lines) and Tajima’s D (solid red lines) for two selected loci: the *FLK* (left) and the *CYP78A9* (right). *FLK* shows a signature of selection (low  $\pi$  and negative Tajima’s D) in the European population, while *CYP78A9* shows a signature of selection in both Europe and India. Dashed lines indicate genome-wide averages for  $\pi$  (black) and Tajima’s D (red).

meiosis<sup>96</sup> and are increased during male gametogenesis, CHH methylation is highly accumulated during embryogenesis<sup>18,24–26</sup>. In facultative asexual plants, due to reduced sexual reproduction and meiosis, the selection of genetic mechanisms maintaining or increasing the CpG, CHG and CHH methylation is reduced or absent, which might have led to the reduced CpG, CHG and CHH methylation levels. Consistently, a recent study suggests that *S. polyrhiza* has lost several genes in the RdDM pathway<sup>41</sup>. Interestingly, within species, the CHG and CHH methylation profile of the 20 individuals largely correlates with their genetic distance (Supplementary Fig. 13 and 14), indicating a gradual neutral evolution of DNA methylomes in *S. polyrhiza*. For example, the Indian and European populations, which diverged from SE-Asian populations around 51,000 and 12,000 generations ago, gradually decreased their CHH methylations (Fig. 3a–c).

At the species level, using a genome-wide scan approach, we found a strong signature of natural selection on genes involved in flower and seed development, indicating that the evolution of reproduction, likely, an increased clonal propagation in *S. polyrhiza*, was driven by natural selection. This is consistent with the pattern that many aquatic organisms reproduce clonally<sup>97</sup>. In addition, several genes related to vascularity, root development and DNA damage repair were also under strong selection, suggesting the reduced root and vascular development and low mutation rate in *S. polyrhiza* were likely also driven by natural selection.

Among populations, we found strong positive selection on genes involved in sexual reproduction and development in India and Europe populations, two recently evolved populations that showed reduced genomic recombination. These results are consistent with the hypothesis that natural selection favors clonal reproduction in *S. polyrhiza* during the recent colonization process, a pattern that was frequently found in many invasive species<sup>98,99</sup>. However, despite strong selection favoring clonal reproduction, substantial recombination in the *S. polyrhiza* genome, mostly in the SE-Asian population, remained, reflecting that sexual reproduction is essential to overcome the costs involved in clonal reproduction in the long term.

Taken together, the structure of population genomes and epigenomes of *S. polyrhiza* suggest that demography and natural selection acting on the reproduction system and organ development can shape genome-wide genomic and epigenomic variations.

## Materials and Methods

### DNA sample preparation and sequencing

We sequenced 131 genotypes that were primarily collected from Asia and Europe (Supplementary Data 1). These samples were cultivated in N-medium<sup>100</sup> until DNA isolation using a CTAB method. Library preparations were carried out following the protocol described in Xu et al.<sup>36</sup>. All libraries were sequenced either on Illumina HiSeq X Ten or Illumina HiSeq 4000 platforms for paired-end sequencing with a read size of 150 bp. Low-quality reads and adapter sequences were trimmed with AdapterRemoval (v2.033)<sup>101</sup>. On average, 33.8 million reads per genotype were obtained. The clean reads were aligned to the *S. polyrhiza* reference genome<sup>48,102</sup> using BWA-MEM (<https://github.com/lh3/bwa>) with default parameters. Reads without alignment hits or with multiple alignment positions were removed. SAMtools “rmdup” function was used to remove PCR duplicates<sup>103</sup>.

### Genetic variant identification and gene family annotation

After filtered out low-quality SNPs using GATK<sup>104</sup> (v4.1.4.1, Java 11) with options: “QD < 2.0 | QUAL < 30.0 | SOR > 3.0 | FS > 60.0 | MQ < 40.0 | MQRankSum < -12.5 | ReadPosRankSum < -8.0”, we identified 8,363,387 SNPs. Then, VCFtools (v0.1.13)<sup>105</sup> and GATK were used to remove SNPs that have the following features: (1) SNPs from organelle genomes (9,278 SNPs); (2) missing genotypes >20% (85,645 SNPs); (3) mean sequencing depth <8 or >41 (179,920 SNPs); (4) non-biallelic (448,404 SNPs); (5) minor allele frequency (MAF) <1% (6,102,027 SNPs); and finally, (6) located in small SNP clusters ( $\geq 3$  SNPs in a ten base-pair window, accounted for 296,132 SNPs). We updated the protein-coding gene annotation of *S. polyrhiza* based on recently published transcriptomes and Iso-seq data (see Supplementary Methods Section 1.1, Supplementary Results Section 2.1,

Supplementary Table 9, and Supplementary Figs. 18–20). We used SnpEff (version 5.0c)<sup>106</sup> to annotate SNPs and INDELS. To exam whether SNP cluster filtering criterion affects the estimation of genomic diversity and selection, we performed additional analyses based on a more relaxed filtering parameter ( $\geq 200$  SNPs in 1 Kb region). Although the second SNP cluster filtering criterion resulted in 18.7% more SNPs, which are mostly (>88%) located in TE regions or nearby the SV or INDELS, the patterns of genomic diversity and selection did not change. In addition to SNPs and INDELS, We identified SVs using a joint genotyping pipeline and stringent quality filtration processes (see Supplementary Methods Section 1.2, Supplementary Results Section 2.2, and Supplementary Fig. 21–24).

We estimated genome-wide nucleotide diversity ( $\pi$ ) and genome-wide  $\pi_N/\pi_S$  ratios using SNPgenie (v2019.10.31)<sup>107</sup>. The SNPs overlapping with the structure variations were excluded from the calculation to minimize potential interference caused by misalignments, ensuring a more accurate and reliable analysis.

The genome-wide heterozygosity for each individual was calculated using VCFtools (v0.1.13)<sup>105</sup>. We estimated the genetic associations between heterozygosity and the SVs of *AGL62* and *SOC1* using RVTESTS<sup>108</sup> with the single variant Wald test.

To study the potential genetic factors related to the variation of sexual reproduction frequency in *S. polyrhiza*, we annotated the MADS-box gene family (see Supplementary Methods Section 1.3 and Supplementary Results Section 2.3, Supplementary Fig. 25–27, Supplementary Table 10, and Supplementary Data 12). Other gene families that were annotated in Arabidopsis were also identified in *S. polyrhiza* using an orthology-based method (see Supplementary Methods Section 1.4 and Supplementary Data 4).

### Population structure and linkage disequilibrium (LD)

We grouped genetically similar genotypes by defining clonal genotype pairs that have no more than 0.01% different homozygous sites and no more than 2% different heterozygous sites. These thresholds were previously adopted by Ho et al.<sup>37</sup>.

Prior to the population structure analysis, we removed SNPs that (1) deviated from Hardy-Weinberg Equilibrium (Fisher exact test,  $P < 0.01$ ) or (2) linked loci (each pair of SNP have correlation coefficient  $r^2 > 0.33$  in a sliding window with a size of 50 SNPs and step of 5 SNPs), using VCFtools (v0.1.13)<sup>105</sup> and Plink (v1.9)<sup>109</sup>.

Principal component analysis (PCA) and population structure analysis were carried out using Plink (v1.9)<sup>109</sup> and fastStructure (v1.0)<sup>110</sup>, respectively. The simple mode (as default) from fastStructure was used for the population structure analysis. The K value was estimated using a heuristic function in fastStructure.

For each of the 159 clonal families, we selected the least missingness genotype (i.e. the genotype with the highest sequencing coverage of that clonal family) as the representative genotype. SNP information from all 159 representative genotypes was used to estimate the linkage disequilibrium decay for each of the four populations. PopLDdecay (v3.41)<sup>111</sup> was used to measure LD decay. For each population, we used the following filters: SNP of missing allele > 20% and MAF < 0.05. The allele frequency correlation (denoted as  $r^2$ ) of pairwise SNPs within 100 kb physical distance was calculated.

### Phylogenetic tree reconstruction

We used BLAST+ version 2.9.0<sup>112</sup> to identify orthologous fragments between the genomes of *S. polyrhiza* and *Colocasia esculenta* (Araceae). For each SNP from the core set, the reference allele and its flanking 300 bp (upstream 150 bp and downstream 150 bp, respectively) sequences were extracted from the *S. polyrhiza* genome and then aligned to the *C. esculenta* reference genome<sup>113</sup>. The hit thresholds were set as (1) alignment identity >70%; (2) e-value >  $1e-6$ ; (3) minimum aligned sequence length  $\geq 50$  (the aligned sequence must cover SNP position); (4) keep the best hit; and (5) ignore short deletions from *C. esculenta*. The orthologous alleles from *C. esculenta* were used as the outgroup genotype. We identified only 13,120 SNPs that have orthologous fragments in the *C. esculenta* genome. Those data were further used to infer the maximum-likelihood

(ML) phylogenetic tree using RAxML-ng (v1.0.1)<sup>114</sup>. The best hit model was estimated to be “TVM + G4” using Modeltest-ng (0.1.6)<sup>115,116</sup>. The bootstrapping converged after 700 iterations of the ML tree search. ITOL v5<sup>117</sup> and the Python package ETE2<sup>118</sup> were used for tree visualization.

### Selection analysis

Genome-wide scans of selection were performed on all 20 chromosomes of all sampled populations. Selective sweeps were inferred by three programs: RAISeD<sup>61</sup>, SweeD<sup>62</sup> and LASSI<sup>63</sup>. RAISeD uses the  $\mu$  statistic, which provides information on the SFS, LD, and genomic diversity to evaluate the presence of positive selection<sup>61</sup>. SweeD calculates the traditional composite likelihood ratio (CLR) to infer loci under selection<sup>62</sup>. LASSI employs the  $T$  statistic, which uses a likelihood model based on the haplotype frequency spectrum to detect hard and soft sweeps<sup>63</sup>. As recommended by the authors of LASSI, we selected the top 5%  $T$  scores as candidates for selection. For RAISeD and SweeD we selected the top 1% scores. After finding the common genes under selection according to all three programs, we reported the genes that have orthologs in *A. thaliana*. The embryo lethal genes from *A. thaliana*<sup>119</sup> were used for the enrichment analysis.

To test for population/branch-specific signals of selection, we ran a composite likelihood ratio (CLR) approach as implemented in 3P-CLR<sup>120</sup>. Briefly, this method uses three-population trees coupled with genomic data as input, from which patterns of linked allele frequency differentiation are calculated. By doing this, this algorithm can tell apart signals of selection that happened in either branch of the tree or in the ancestral lineage, as well as outputting the loci with the highest CLR<sup>120</sup>. In our case, we used either a North America-Asia-Europe, or a North America-Asia-India population tree as input, and 3P-CLR output the CLR across windows along each chromosome in the *S. polyrhiza* genome. We then selected the top 1% windows for each branch of the input tree and reported the genes that are present in each window. To further validate the evidence of positive selection on the regions with the highest CLR, we ran scans of Tajima’s  $D$  and genomic diversity along the same windows and contrasted them with the same signal along the other population branches. We expect negative Tajima’s  $D$  and low genomic diversity values along the populations with high CLR values. For authenticity validation of genes under selection, we used RT-qPCR to check the expression of eight genes (see Supplementary Methods 1.9, Supplementary Results 2.8, Supplementary Fig. 28, and Supplementary Table 11 and 12). Another expanded list that includes 37 candidate genes was also created, and these genes’ expression (RNA-seq) and orthology alignments against their Arabidopsis counterparts were examined (Supplementary Data 7).

### DNA methylation in *S. polyrhiza*

We selected five genotypes from each of the four populations (America, India, SE-Asia, Europe) for single-base whole-genome bisulfite sequencing (WGBS). The genotypes originated from distinct clonal families, except for two European genotypes that came from the same clonal family (Supplementary Table 7).

FastQC (v0.11.5, <https://www.bioinformatics.babraham.ac.uk/projects/fastqc/>) was used to summarize statistics of the sequencing reads. Trimmomatic (v 0.36)<sup>121</sup> was used to filter out low-quality reads with the parameters “SLIDINGWINDOW: 4:15, LEADING:3, TRAILING:3, ILLUMINACLIP: adapter.fa: 2: 30: 10, MINLEN:36”. To account for the genetic variations among genotypes, we generated pseudo-reference genome for each genotype by substituting SNP from the *S. polyrhiza* reference genome using GATK, using a similar strategy to previous studies<sup>122,123</sup>. Bismark (v 0.16.3)<sup>124</sup> was used to align bisulfite-treated reads to pseudo-reference genomes. Identical reads aligned to the same genomic regions were deemed as duplicated reads and thus were removed. Cytosines covered by less than five sequencing reads were excluded from the study. Only after applying these filters the sequencing depth and coverage were then summarized. The sodium bisulfite non-conversion rate was calculated as the percentage of non-converted cytosines to all cytosines in the reads that mapped to the chloroplast genome<sup>125</sup> (GenBank: JN160603.2). For each cytosine site, a binomial test was performed to determine if the cytosine was methylated. If the methylation frequency at

the site was lower than the background, which was estimated as the non-conversion rate, then the site was considered unmethylated, and the reads supporting methylation at this site were excluded<sup>126</sup>.

We calculated two different methylation parameters: the proportion of methylated cytosines (mC methylation) and weighted methylation level (wML)<sup>126</sup>. For both parameters, only cytosines covered by more than four sequencing reads were involved in the calculation. Those cytosines with low reads supporting methylation but not passing the binomial test were considered as un-methylated cytosines. The mC proportion was calculated by dividing the number of methylated cytosines by the total number of cytosines. Genomic regional wML was calculated using the methylKit (v1.17.5)<sup>127</sup> and the regioneR (v1.28.0)<sup>128</sup>, with input based on the cytosine report generated with the Bismark pipeline. Line plots that show the wML patterns across the gene body and transposable elements, as well as their 2 kb flanking regions, were generated using ViewBS (v0.1.11)<sup>129</sup>. The hierarchical clustering, based on the methylation profiles’ similarity, was done using methylKit. The comparison between the genetic phylogenetic tree and hierarchical clustering based on the methylome was made using the R packages ggtree (v3.4.4)<sup>130</sup>, treeio (v1.20.2)<sup>131</sup>, ape (v5.6.2)<sup>132</sup>, and phytools (v1.2.0)<sup>133</sup>.

### Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

### Data availability

The raw genomic and bisulfite sequencing reads involved in this study can be retrieved from NCBI under accession numbers Bioproject PRJNA701543 and Bioproject PRJNA934173. The scripts for the data analyses are deposited in [https://github.com/Xu-lab-Evolution/Great\\_duckweed\\_popg](https://github.com/Xu-lab-Evolution/Great_duckweed_popg). The authors declare that the data and corresponding computational codes supporting the conclusions of this study are available within the article and its supplementary information file.

## Acknowledgements

We thank Martin Schäfer, Marie Sárazová, and Laura Böttner for supporting plant sample maintenance and DNA isolations. We thank Arturo Mari-Ordóñez and Pavlos Pavlidis for valuable comments and Alex Widmer for contributing resources at the early stage of this project. This project is supported by the German Research Foundation (427577435 and 438887884 to S. X. and 422213951 to M. Hu.), the Center for Adaptation to a Changing Environment (ACE) at ETH Zurich (to S. X.), the Swiss National Science Foundation (P400PB\_186770 to M. Hu.), the Volkswagen Foundation (97236 to M. Hu.) and through career development measures of the University of Münster (to M. Hu.) The project was inspired by discussions with the members of the CRC TRR 212 (NC3) – Project number 316099922, and Research Training Group 2526 (GenEvo) – Project number 407023052. Parts of this research were conducted using the supercomputer Mogon and/or advisory services offered by the Johannes Gutenberg University Mainz (hpc.uni-mainz.de), which is a member of the AHRP (Alliance for High-Performance Computing in Rhineland Palatinate, [www.ahrp.info](http://www.ahrp.info)) and the Gauss Alliance e.V. The authors gratefully acknowledge the computing time granted on the supercomputer Mogon at the Johannes Gutenberg University Mainz (hpc.uni-mainz.de) and PALMA-II at the University of Münster.

## Author contributions

Y. W., P. D. and S. X. performed data analysis. A. C. and M. Ho. performed the experiments. K. J. A., H. Z., K. S. S., and S.X. contributed to the giant duckweed collections and resources. S. X. and M. Hu. conceived and supervised the project. S. X., Y. W., P. D., A. C. and M. Hu. wrote the manuscript. All authors contributed to the final version of the manuscript.

## Funding

Open Access funding enabled and organized by Projekt DEAL.

## Competing interests

The authors declare no competing interests.

## 4 Conclusion and Outlook

### 4.1 Concept of Non-Targeted-Site Resistance Evolution in Plants

In line with earlier reports (Goggin et al. 2018; Szigeti 2005), we discovered a large amount of phenotypic variation in herbicide resistance in *S. polyrhiza*. The first report on natural variation in herbicide resistance dates back to the year 1957, documenting a case of resistance to 2,4-D in *Daucus carota* (Switzer 1957; Whitehead and Switzer 1963). Since 2,4-D was commercially introduced in modern agriculture around ten years before (Peterson et al. 2015), the emergence of this first resistance case indicates that herbicide resistance evolution occurs in short evolutionary time scales. In the case of *Raphanus raphanistrum* variation in resistance mechanisms was also discovered in several ecotypes coexisting in one location (Goggin et al. 2018). Since susceptible populations also varied in terms of herbicide degradation speed (Goggin et al. 2018), these findings suggest the possibility of natural variation in herbicide resistance prior to herbicide introduction in modern agriculture.

A possible explanation for this is that adaption to environmental stress factors was also shown to influence the efficiency of herbicide-based weed control (Radchenko et al. 2021). In this regard, several environmental adaptations were shown to influence herbicide resistance. For instance, increased leaf thickness, which is an adaptation to elevation (see section 1.1) (Halbritter et al. 2018) and stomatal closure were shown to reduce the uptake of glyphosate (Ziska and Teasdale 2000; Kumar et al. 2023). Since temperature strongly influences degradation kinetics and phloem transport of herbicides (Kumar et al. 2023; Godar et al. 2015), temperature-driven adaptation of these processes could have a potentially strong impact on herbicide efficiency. Also, plants were shown to have decreased requirements of aromatic amino acids for protein synthesis under high CO<sub>2</sub> levels (Taub et al. 2008; Kumar et al. 2023). Since glyphosate acts through inhibition of aromatic acid biosynthesis, decreased protein synthesis in adaptation to high CO<sub>2</sub> levels might promote the evolution of glyphosate resistance (Kumar et al. 2023).

On a molecular level, plant stress responses to factors like drought, water stress, UV-radiation and herbicides follow the same scheme, which usually involves four steps of stress adaptation: alarm, acclimation, resistance, exhaustion/recovery (Keith et al. 2017). Consequently, plants with upregulated stress responses also showed increased resistance to herbicides (Keith et al. 2017; Dyer 2018; Lee et al. 2007; Kwon et al. 2003). This mechanistic similarity suggests an evolution of herbicide resistance through pleiotropy from genes coordinating stress responses (Figure 5). As a consequence of these molecular changes in stress-responses, several cross-

resistances between herbicides and non-anthropogenic stress factors were reported. For instance, paraquat resistant plants showed elevated resistance to heat stress (Tang et al. 2006) and H<sub>2</sub>O<sub>2</sub> (Kwon et al. 2003). Together, these strong mechanistic similarities suggest an evolution of herbicide resistance mechanisms from stress-response pathways (Figure 5).

Since changes in stress-response are polygenic and, therefore, evolve gradually (Keith et al. 2017), the identification of multiple intermediate resistance levels in our study (Höfer et al. 2024a) highlights that future studies on the evolution of herbicide resistance cases should focus on a large-scale characterization of genotypes with intermediate resistance levels. As resistance traits can be continuous (Goggin et al. 2018), just studying extreme phenotypes, as done in many previous studies (Dinelli et al. 2006; Ge et al. 2010; Jóri et al. 2007), will therefore give an incomplete picture of the trajectory of resistance evolution. Also, because resistance modes can vary on species level (Szigeti 2005), characterization of intermediate resistant genotypes might reveal which environmental settings favor the evolution of certain resistance modes.

Since herbicide resistance cases are causing huge economical costs (Oerke 2006), several strategies can be applied to avoid resistance evolution. One strategy could be to not or only minimally rely on herbicide-based control and instead focus on traditional techniques like the removal of weeds (Vats 2015) or microbial biological control strategies (Heap and Duke 2018) as alternatives. Since resistant weed populations only cause damage when spreading significantly in natural populations, monitoring of resistant weeds in populations via molecular genetic methods might become crucial in modern agriculture. Once a critical distribution of resistant weeds is reached, stubble burning can be applied to slow down the spread (Zia-Ul-Haq et al. 2019). Frequent crop rotations, which disrupt the life cycles of resistant weeds through tilling of land, can help to prevent the spread of resistant weeds (Vats 2015). In a similar way, the rotation of herbicides with different sites and modes of action can prevent the evolution of target-site resistance cases (Vats 2015; Heap and Duke 2018).

**Figure 5: Theory for explaining the origin of natural variation in herbicide tolerance for *Spirodela polyrhiza*.** A: Among different genotypes of *S. polyrhiza*, genotype 3 shows the best adaptation to environmental stress factors such as UV-light, herbivory, drought, and salinity, due to faster upregulation or higher constitutive expression of intrinsic stress response pathways. B: Through effects like the production of reactive oxygen species, leaf desiccation and chlorosis herbicides cause similar stress symptoms as non-anthropogenic stress factors. Therefore, plants showing increased tolerance to environmental stress factors like genotype 3 are more likely to survive doses of herbicides, lethal to less well-adapted plants like genotypes 1 and 2.

## 4.2 Optimization Strategies for Growth and Defense

Besides controlling for herbicide-resistant weeds, optimization of balance between growth and specialized metabolite production is of central importance for maximizing crop yield (Huot et al. 2014). According to the resource-drain hypothesis, one would expect strong negative associations between all specialized metabolites on the one site with growth and primary metabolites on the other site. However, many previous studies, including our own study of

metabolite levels in *S. polyrhiza* (Höfer et al. 2024b) found multiple positive associations of specialized metabolite contents with plant growth and primary metabolism (Aftab et al. 2010; Zhang et al. 2024; Ringli et al. 2008), suggesting that the concept of growth-defense tradeoffs does not apply strictly for plants.

An explanation for this is, that costs for the synthesis of secondary metabolites are very unequal among specialized metabolite classes (Neilson et al. 2013; Foyer et al. 2007), which is why certain defensive metabolites like cyanogenic glycosides also play an important role as sinks for carbohydrates and nitrogen (Neilson et al. 2013). Apart from this, growth reduction during exposure to stresses was hypothesized to be caused by a genetic mechanism to protect the replication machinery of DNA from damage during this vulnerable stage (Foyer et al. 2007). Here, often genes regulating plant immunity and pathogen resistance mediate growth-defense tradeoffs (Gao et al. 2024). An example for this are *NLRs* (*NUCLEOTIDE-BINDING LEUCINE-RICH REPEAT*), which encode for receptors recognizing pathogen effectors (Wang et al. 2019a). Overexpression of *NLRs* in susceptible cultivars confers resistance to blast disease in rice but causes dwarf phenotypes through growth delay (Wang et al. 2019a; Gao et al. 2024). The pleiotropic character of some immune genes offers the possibility to improve growth and defense at the same time. The first pleiotropic gene discovered to improve both growth and defense simultaneously was *IDEAL-PLANT ARCHITECTURE 1* (*IPAI*), which encodes a regulator of plant immunity (Wang et al. 2018). During pathogen infection *IPAI* is activated through phosphorylation and initiates the induction of NLR-mediated immunity (Wang et al. 2018). Whereas in the absence of pathogens, *IPAI* is dephosphorylated and promotes plant fertility through increasing grain yield (Wang et al. 2018). Overexpression of *IPAI* leads to an increase in the magnitude of this response, increasing both yield and plant resistance to fungal infection (Wang et al. 2018).

Another possibility for overcoming growth-defense tradeoffs is to express pathogen resistance-conferring genes under the control of disease-inducible promoters. Since permanent expression of pathogen resistance genes decreases plant fitness, growth-defense tradeoffs can be overcome through transcriptional or translation suppression of defense-associated genes under constitutive conditions. As an example for this, the facultative translational suppression during pathogen absence of the immune gene *NONEXPRESSOR OF PATHOGENESIS-RELATED GENES 1* (*NPRI*) leads to increased resistance without additional fitness costs (Xu et al. 2017). Growth-defense tradeoffs can also be influenced through the suppression of certain regulatory micro-RNAs targeting RNA-induced silencing complex proteins. Here, suppression of miR168

which targets the argonaut protein *AGO1* was shown to improve yield, shorten flowering time and increase immunity simultaneously (Wang et al. 2021).

Together, these findings suggest that growth-defense trade-offs can be optimized in plants through reverse engineering of pleiotropic gene candidates controlling plant immune responses.

### **4.3 Genetic Control of Immunity and Growth in *S. polyrhiza***

From all GWAS candidates associated with metabolic traits, we identified a total of five candidate genes to be under population-wide selection within the SE-Asia or India duckweed populations (Table 1). For two of these candidates (*SpGA2022\_010583*, *SpGA2022\_007797*) no functional homologs were identified (Table 1). Homologs of the remaining three candidate genes showed potential involvement in pathogen resistance (*SpHPL*, *SpSCAMP3*) (Wang et al. 2020; Lu et al. 2021) and cell division (*SpYPEL*) (Hosono et al. 2010). All three candidates were associated with cytokinin levels. Since cytokinins play a crucial role in the allocation of defense resources (Brütting et al. 2017), these candidate genes might explain natural variation in duckweed pathogen resistance. This would make them potential candidates for optimization of growth-defense tradeoffs in *S. polyrhiza*.

Knock out of the *HYDROXY-PEROXIDE LYASE 3 (HPL3)*, an homolog of *SpHPL*, leads to the induction of defense gene expression and increased resistance to herbivorous insects at the expense of decreased seed size and seed weight (Wang et al. 2020). Functionally, HPL3 plays a central role in the oxylipin pathway, producing green-leave volatiles (Farmer and Goossens 2019). Thereby, HPL competes with the allene oxide synthase (AOS) for their common substrate 13-hydroperoxy octadecatrienoic (Farmer and Goossens 2019). Since AOS is involved in the biosynthesis of jasmonic acid, the loss of function of HPL3 is thought to trigger the observed allocation of resources from growth to defense through an increase in jasmonate levels (Wang et al. 2020).

In contrast to this *SCAMP3 (SECRETORY CARRIER MEMBRANE PROTEIN 3)* was shown to function as a host factor regulating virus replication (Lu et al. 2021). Located within Golgi membranes, SCAMP3 participates in intracellular protein transport through vesicles (Lu et al. 2021). Such vesicular transport processes are relevant for defense functions in two ways. First, vesicles can act through the secretion of immune molecules in extracellular space for pathogen defense (Yun et al. 2023). Second, vesicles can function as replication organelles for viruses (Lu et al. 2021). Since suppression of *SCAMP3* expression decreases virus replication, it is

thought to play a central role in the interaction between viral surface protein and the vesicles functioning as replication organelles (Lu et al. 2021).

With *SpYPEL* (*YIPPEE-LIKE PROTEIN*), we identified a gene whose homologs were functionally involved in cell cycle progression and growth (Hosono et al. 2010; Han et al. 2018). *YPELs* are thought to have important functions in mitosis, since they were shown to move from the nucleus to the spindle midzone during initiation of cell division (Hosono et al. 2010). Because of that, knockouts of *YPELs* were shown to lead to growth defects through reduction of cell division rate on a systemic level (Hosono et al. 2010; Han et al. 2018).

Since *SpHPL*, *SpSCAMP3* and *SpYPEL* were identified to be under population-wide selection and markers in close distance to these genes were associated with cytokinin levels, which control resource allocation to either growth or defense, our results indicate that functional variation in these genes might be relevant for genotype-specific differences in growth and defense for *S. polyrhiza*. However, further reverse genetic studies are required to elucidate the exact potential of these genes for the optimization of growth-defense tradeoffs in *S. polyrhiza*.

**Table 1: GWAS candidates under population-wide selection.** All candidate genes were identified in GWAS conducted on free metabolite contents of *S. polyrhiza* (Höfer et al. 2024b).

Gene	Annotation	Marker-type	Marker-location	P-Wald	Associated metabolite(s)	Population-wide selection
<i>SpGA2022_009939</i>	<i>SpYPEL</i> (YIPPEE-LIKE PROTEIN)	54 bp deletion	10473 bp upstream of <i>SpGA2022_009939</i>	$2.16 \cdot 10^{-6}$	N <sup>6</sup> -Isopentenyl adenin	SE-Asia
<i>SpGA2022_054953</i>	<i>SpSCAMP3</i> (SECRETORY CARRIER-ASSOCIATED MEMBRANE PROTEIN 3)	76 bp duplication	3'-UTR of <i>SpGA2022_054953</i>	$6.73 \cdot 10^{-7}$	cis-Zeatin	India
<i>SpGA2022_010583</i>	-	G/C transversion	Intronic region of <i>SpGA2022_010583</i>	$3.51 \cdot 10^{-6}$	Chlorogenic acid	SE-Asia

#### 4.4 Studying the Evolution of Plant Mating Systems

Overall, our work identified many genes controlling mating system to be under population- or species-wide selection, suggesting population-specific differences in flowering rates in *S. polyrhiza* (Wang et al. 2024). Strong population-based variation in sexual reproduction rates was already described previously (Whitehead et al. 2018), indicating that most plants don't follow a single mating strategy, exclusively.

Such intraspecific variations in plant mating systems provide the basis for future selection pressures can act on. For example, human land-use often affects habitat fragmentation in natural ecosystems, impacting the evolution of plant mating systems through changes in plant-pollinator interactions (Eckert et al. 2010). Increased grazing during agricultural land-use was shown to decrease outcrossing (Stout 2014). Inbreeding caused by reduced outcrossing rates might then promote herbicide resistance by applying stronger purifying selection on susceptible alleles (Kuester et al. 2017)

Also, global warming-driven migration events of warm-adapted species in temperate climates cause an overall biotic homogenization (Montràs-Janer et al. 2024). During rapid species

expansion, clonally reproducing species might be favored (Wang et al. 2024), as discussed in section 1.2.2. A consequence of clonal reproduction is a low mutation rate and reduced diversity (Baggs et al. 2022). The accumulation of deleterious mutations due to clonal growth causes gene losses, leading to trait reduction in plants (Baggs et al. 2022; Johnson et al. 2015).

Besides these above-mentioned predictions on future evolutionary trajectories, many aspects of mating system evolution are still unclear, hampering our understanding on evolution of new plant phenotypes.

Many plant reproductive traits are plastic and are strongly influenced by environmental features (Stearns 1989). However, the identification of natural flowering conditions in *S. polyrhiza* might provide valuable insights into the evolution of mating systems in Lemnaceae. Since *S. polyrhiza* is world-wide distributed (Tippery and Les 2020), flowering traits might be induced by various environmental setups depending on the specific genotype, making it difficult to explore environmental conditions that promote flowering in nature on the species level. One way to experimentally study the impact of environmental conditions on flowering in *S. polyrhiza* would be through a translocation experiment (Whitehead et al. 2018) to expose various genotypes from different genetic populations to a broad array of natural environments and monitor flowering rates in nature.

Another important aspect determining the success of sexual reproduction in plants is the seed germination rate, which was shown to vary greatly among duckweed species (Landolt 1986). Since germinating seeds differ from non-germinating seeds regarding their microbial compositions (Acuña et al. 2023), the presence of microbiota benefitting seed germination might be a key factor controlling mating system evolution in plants. In *D. carota*, bacteria associated with pathogen defense and nitrate reduction were associated with seed germination (Acuña et al. 2023), indicating that microbial communities can shape the duration and efficiency of plant sexual reproduction through seed germination. Future work should, therefore, also focus on how bacterial communities shape seed germination in duckweed.

Another important question is how stochasticity shapes the evolution of mating systems. For instance, bottle neck effects were shown to increase stochasticity in mating system evolution, promoting inbreeding effects (Karron et al. 2011). This suggests that reproductive systems can also evolve randomly in nature depending on the population size.

Finally, deeper understatement in the genetic basis of the duckweed mating system will require access to reverse genetic methods, allowing knock-out and overexpression of the identified gene candidates to verify their exact functions in duckweed sexual reproduction.

## 6. Acknowledgements

This thesis occupied a major portion of the past five years of my life. In this process, I greatly enjoyed the highly supportive environment provided by my colleagues and friends. Therefore, I would like to take this opportunity to thank the AG Xu for providing a supportive environment, that enabled me to conduct this research. In this regard, I am especially thankful to [REDACTED], [REDACTED] and [REDACTED]. As supervisor of my PhD project [REDACTED] provided a very inspiring research environment and a great scientific advice, through which I could improve my communication and writing skills. Furthermore, he provided the basic research concept and organized the funding's for this project. Many thanks also to [REDACTED], from whom I gained lots of interesting input about GWAS and population genetics through extensive scientific discussions. Through his great reliability and openness [REDACTED], greatly contributed to most of the research associated with this thesis. He has been of great help during the screening of herbicide resistant genotypes and provided support in the identification of GWAS candidates. Also, outside of the office, he is a great friend to me, joining most of my board game evenings. A large portion of this thesis is associated with chemical metabolite analysis conducted via LC-MS. These metabolite studies would not have been possible without the help of [REDACTED]. Through establishing extraction and analysis protocols for antioxidants, free metabolite and diquat measurements, he enabled the analysis of metabolite contents in duckweed tissue. I am also thankful to the technicians [REDACTED], [REDACTED] and [REDACTED], who helped maintaining the duckweed collection. Special thanks also go to my student helpers, [REDACTED] and [REDACTED], who provided great help during the cultivation and screening of duckweed genotypes. [REDACTED] also extracted free metabolites from duckweed genotypes together with [REDACTED]. I am thankful to [REDACTED] for introducing me into the field of plant genetic manipulation and callus-cultivation. Finally, I would like to thank [REDACTED] and [REDACTED] for co-supervising this thesis and providing helpful comments. In the AG Finkemeier, I thank [REDACTED] for helping we with the chlorophyll measurements in duckweed.

## 7. Versicherung

Anlage zum Antrag auf Zulassung zur Promotionsprüfung  
gem. § 12 der Promotionsordnung des Fachbereichs Biologie  
der Johannes Gutenberg-Universität Mainz vom 01.04.2018

### VERSICHERUNG

Name: Martin Höfer

Hiermit versichere ich gemäß § 12, (2) der Promotionsordnung vom 01.04.2018:  
(zutreffendes ist angekreuzt.)

- Ich habe die heute als Dissertation vorgelegte Arbeit selbst angefertigt und ausschließlich die angegebenen Quellen und Hilfsmittel verwendet.
- Ich habe oder hatte die jetzt als Dissertation vorgelegte Arbeit noch an keiner anderen deutschen oder ausländischen Hochschule oder vergleichbaren Einrichtung zur Erlangung eines akademischen Grades eingereicht.
- Ich habe noch kein Promotions- PhD,- oder ein vergleichbares Graduerungsverfahren im Promotionsfach erfolglos beendet.
- Ich habe noch kein Promotions- PhD,- oder ein vergleichbares Graduerungsverfahren im Promotionsfach erfolgreich beendet.
- Für die Anfertigung der vorgelegten Arbeit wurde keine entgeltliche Hilfe Dritter, insbesondere eine Promotionsberatung oder -vermittlung in Anspruch genommen.

Mainz, den 29.10.2024

(Unterschrift)

## **8. Curriculum vitae**

# Martin Höfer

## personal data

address: Rüsselsheimer Allee 86,  
55130 Mainz  
telephone: 0174 2511827  
place and date of birth: Saalfeld, 10.03.1995  
E-Mail: mahoefer@uni-mainz.de

## education

### university

Feb. 2020 – Jan. 2025 (expected) **PhD studies**, Westfälische Wilhelms-University, Münster and Johannes-Gutenberg University, Mainz, expected finish in Jan. 2025

Oct. 2019 – Jan. 2020 **Vocational orientation** aiming to find a PhD position

ct. 2017 – Oct. 2019 **Master studies in chemical biology**, Friedrich Schiller University, Jena (average mark: 1.5)

Oct. 2014 – Sept. 2017 **Bachelor studies in biochemistry/molecular biology**, Friedrich Schiller University, Jena (average mark: 1.7)

### school

2005 – 2014 **graduation: Abitur (A - level)**  
comprehensive school: IGS Grete Unrein, Jena

## professional experiences

Feb. 2020 – Jan. 2025 (expected) **PhD thesis**, group: Plant Adaption-in-action at the Institute of Evolution and Biodiversity, Münster (till March 2022) and Institute of Organismic and Molecular Evolution, Mainz (since April 2022)  
Title: Genetic Basis of Metabolic Trait Variation in the Giant Duckweed *Spirodela polyrhiza* (Lemnaceae)  
Supervision: [REDACTED], [REDACTED]

Jan. 2019 – Oct. 2019 **Master thesis**, group: Chemical ecology of cross kingdom interactions at the institute of inorganic and analytical chemistry, Jena

title: Development of molecular tools to study the genetic basis of the morphogenesis of the marine macroalgae *Ulva mutabilis*

supervision: [REDACTED], [REDACTED]  
[REDACTED]

Oct. 2019 – Jan. 2020

**Vocational orientation** aiming to find a PhD position

Oct. 2018 – Dec. 2018

**Internship on NGS techniques** in microbiome research in the Department of Host Septomics at the ZIK Septomics, Jena

Sept. 2017 – Feb. 2018

**Research assistant** in the Department of Biochemistry at the Max-Planck Institute of chemical ecology, Jena

Mar. 2017 – Aug. 2017

**Bachelor thesis**, Department of Biochemistry at the Max-Planck Institute for chemical ecology, Jena  
title: Characteristic of the effects of Copper excess on metabolic and oxidative parameters in *Spirodela polyrhiza*  
supervision: [REDACTED], [REDACTED]

Oct. 2016 – Feb. 2017

**Tutor** for an undergraduate student biochemistry lecture

## other experiences

computer skills in Word (very good), Latex (good), Excel (good) and SPSS (basic)

computational skills in R (very good) and Python (basic)

practical experiences in: molecular cloning, cultivation of macroalgae, microbial ecology, LC – MS, quantitative genetics (GWAS), plant tissue cultivation, plant transformation and qPCR

languages: German (native), English (full proficiency), Russian (basic) and Arabic (basic)

## conferences

6<sup>th</sup> International Conference on Duckweed Research and Applications 2022 (poster presentation)

39<sup>th</sup> Annual Meeting of the International Society of Chemical Ecology 2024 ([REDACTED] talk)

## publications

Höfer, M., Schäfer, M., Wang, Y., Wink, S. & Xu, S. Genetic Mechanism of Non-Targeted-Site Resistance to Diquat in *Spirodela polyrhiza*. *Plants*. **2024**, 13, 845, <https://doi.org/10.3390/plants13060845>
